## ABSTRACT

---

# On the Mechanisms of Ability Peer Effects\*

Studying with higher ability peers increases student performance, yet we have little idea why. We exploit random assignment of students to classrooms and find positive peer effects on test scores. With rich data on nineteen potential mechanisms, we then estimate how effects on attitudes, parents, and teachers could drive these results. Higher-achieving peers reduce student effort, increase student university aspirations, increase parental time investments and parental strictness, and have precise null effects elsewhere. None of these mechanisms, however, explain our peer effect on test scores. Our results highlight promising avenues for understanding ability peer effects.

\* We thank David Figlio, Olivier Marie, and especially Jan Feld and Ulf Zölitz for their helpful comments. Boer Xia provided excellent research assistance for this project. Data analyzed in this paper were collected by the research project "Taiwan Education Panel Survey: The First Wave", sponsored by Academia Sinica, Ministry of Education, National Academy for Educational Research and National Science Council. License number: 012018005. The Survey Research Data Archive, Academia Sinica is responsible for the data distribution. The authors appreciate the assistance in providing data by the institutes and individuals aforementioned. We thank the Survey Research Data Archive (SRDA) in Taiwan for providing us with data access, and Wan-wen Su for facilitating our analyses of the Taiwan Education Panel Survey. This research was supported (partially or fully) by the Australian Government through the Australian Research Council's Centre of Excellence for Children and Families over the Life Course (Project ID CE140100027 and CE200100025). The views expressed herein are the authors' own.

# 1 Introduction

Despite an immense literature in economics documenting the importance of peers for academic achievement, there is still much we do not know about their mechanisms. This remains an important limitation in our understanding of the theoretical underpinnings of peer effects, and limits our scope for using class assignment policies as a tool to improve student achievement and educational outcomes (Carrell, Sacerdote and West, 2013; Sacerdote, 2014; Ushchev and Zenou, 2020).

One key reason why it is difficult to make headway in understanding the mechanisms behind peer effects is that this exercise requires large amounts of data from several sources. If we think of educational achievement as the output of an education production function which comprises several simultaneous inputs from students, parents and teachers (e.g. Cunha and Heckman, 2007), it is also natural to think that peers can affect educational achievement through any of these inputs. Datasets that collect information on all, or even many, of these sources are rare. Because of this limitation, the prevailing approach in the empirical literature on academic peer effects is to focus on the effect of higher-achieving peers on the few available outcomes and discuss why these isolated responses may be mechanisms through which academic peer effects operate. Formal analyses of the share of peer effects we can explain are often futile with so few mechanisms to look at, leaving the key unanswered question: what drives academic peer effects?

To answer this question, we need three key elements in the same setting. First, we need to establish their existence; that there is a causal effect of being exposed to higher-achieving peers on students' own academic achievement. Second, we need to observe many potential factors that affect academic achievement. And third, we need to determine whether better peers improve academic achievement by shifting those factors. Many studies have gained access to one or two of these key elements, yet to date there is no study that provides empirical evidence all three of them jointly. We fill this gap.

In this paper, we first show the existence of academic peer effects, as others have done in different settings (for excellent reviews, see Sacerdote (2011, 2014)). We exploit a mandate to randomly assign students to classrooms within schools in our setting as a lynch-pin in our identification strategy, and develop a method to identify and use only schools that adhere to this mandate in our analyses. We find that a one standard deviation (1 SD) increase in the average test scores of classroom peers at baseline increases own test scores by 5.2 percent of a standard deviation two years later.

Using rich data on students, parents, teachers and schools, we then estimate the causal effect of higher-achieving peers on a large battery of student, parent, teacher and school educational inputs, which are all potential mechanisms of academic peer effects. Together, our measures explain 71 percent of test scores two years later which suggest we have a very comprehensive set

of measures in our data. Higher-achieving academic peers decrease students' school effort and increase students' university aspirations and their expected ability to go to university. Higher-achieving peers also increase parents' time investments and strict parenting style. We do not find effects of high-achieving peers on students' initiative in class, truancy, exam cheating, or academic self-efficacy. We also find no effects on parental investments in private tutoring, on emotional support or harsh parenting, or on parental aspirations for their child to go to university. Finally, we also find no effects on students' perceptions of their school environment, or on their teachers' engagement with students, reports of how hard to manage is the classroom, and how tired they feel about teaching. Some of the effects we do find complement existing evidence in the peer effects literature (Feld and Zölitz (2017) on perceived quality of peer interactions; Bursztyn and Jensen (2015) and Bursztyn, Egorov and Jensen (2019) on social pressure and effort provision). Yet most of our estimates explore unstudied mechanisms behind academic peer effects; in fact, no study before has been able to test as many candidate mechanisms as we do.

Combining our estimates of high-achieving peers on score and on educational inputs, we then answer the question: How much of the academic peer effect can be explained by our measured mechanisms? To do this, we begin by estimating the returns of all our educational inputs on academic achievement using high-quality cumulative value-added models (Todd and Wolpin, 2007; Fiorini and Keane, 2014). Our estimates show large returns to many of our explored inputs. We then use these returns to map the effects of higher-achieving peers on educational inputs to academic achievement using mediation analyses (Gelbach, 2016). Our estimates show that our battery of educational inputs mediate a negative share of our academic peer effect—which means that the effects of high-achieving peers on educational inputs make it harder, not easier, to explain academic peer effects. This negative mediation is largely driven by the combined negative effect of high-achieving peers on student effort and its positive value-added returns. Our other inputs explored have a virtually null contribution to mediation. This is a surprising and important new insight for our understanding of academic peer effects and should help guide future research effort understanding their mechanisms.

Finally, we perform an extensive set of sensitivity analyses for our results including: additional tests for conditional random assignment, alternative estimates with an exhaustive set of controls, calculations of the degree of correlated unobserved heterogeneity needed to explain away our findings, corrections for measurement error in student ability and for incomplete sampling of classrooms, inference corrections using randomization inference and multiple hypotheses testing adjustments, and an extensive exploration of heterogeneity in peer effects, and their mediation.

Our paper makes several contributions to better understand the complex nature of academic peer effects. This is the first paper to provide a thorough test of the many possible mechanisms underlying academic peer effects, testing 19 of them covering all key agents in educational production. In one study, we cover the vast majority of achievement peer effect mechanisms—

hypothesized or tested—in this vast literature (see Table 1). Most previous studies test only a few potential mechanisms for academic peer effects but never more than three or four at a time, and never in a formal mediation analysis (though two other studies, Gong, Lu and Song (2019) and Zölitz and Feld (Forth.), use mediation analyses to investigate mechanisms behind the effect of classroom peer gender). This is an important limitation since the many inputs in the education production function imply equally many mechanisms for peer effects to work through, and the only way to know how well we can explain peer effects is to jointly test all these potential mechanisms. The fact that after our efforts we still do not know how academic peer effects work is a testament to their complexity. Our findings rule out a host of mechanisms hypothesized in this extensive literature. When combined with previous findings, our results point to two additional mechanisms (direct peer-to-peer learning and endogenous teaching practices) and one empirical phenomenon (widespread heterogeneity in value-added functions across schools) as the most promising avenues to explain the surprisingly little mediation of academic peer effects.

We also make two methodological contributions to the empirical literature on peer effects. First, we develop an algorithmic approach to conducting balancing tests and identifying non-compliant schools in quasi-experimental peer effect designs. This is particularly useful in settings with partial compliance to random assignment of students to classrooms and no reliable way to know where compliance occurs and where it does not. In such settings, researchers often try and account for systematic violations of random assignment by controlling for additional characteristics beyond balancing characteristics, which complicates the interpretation of peer effect estimates and weakens identification strategies. Our approach is a transparent alternative to improve the validity of quasi-experimental research designs based on conditional random assignment without relying on conditioning pre-treatment covariates to account for failed randomization. Second, we provide a simple algorithm for randomization inference that observes the data structure of students within schools and within classrooms. Maintaining the data structure and, in particular, rigorously respecting assigned classroom sizes is crucial for correctly calculating permutation-based t-randomization p-values (Young, 2019) and for producing permutation-based tests of random assignment, which are commonly used in the empirical peer effects literature. We can provide Stata code for these two procedures upon request.

## **2 Peer Effects in Education**

Economists have been interested in peer effects for a long time, and have published over 100 articles in economic journals since 2009 on peer effects in education alone, 28 of them in top 5 journals.<sup>1</sup> One reason for the widespread interest in peer effects is that they could “*be harnessed to cost-effectively improve public [...] services*” (BenYishay and Mobarak, 2019). In other words, the existence of peer effects implies a social multiplier effect. Inspired by this promise in peer effects, an immense empirical literature rose to provide evidence on their existence and size—notable in education but in other fields as well. After two decades of studies, the existence

of peer effects in education is a well-established fact.<sup>2</sup>

Peer effects are notoriously difficult to identify for two main reasons (Manski, 1993): self-selection into peer groups (i.e., that similar people sort into the same groups) and the reflection problem (i.e., that estimates capture both my effect on my peers and the effect of my peers on me). Self-selection introduces bias in peer effects estimates arising from omitted variables. Reflection ties together the effects of (endogenous) peer interactions with the effect of (exogenous) peer characteristics, complicating the interpretation of peer effect estimates.

Empirical studies typically solve the reflection problem by estimating the reduced-form effect of pre-assignment peer characteristics on student outcomes. Many studies have in addition convincingly solved the issue of self-selection by exploiting quasi-experimental assignment of students to peer groups. Two types of identification strategies have mainly been used to that end. The first strategy leverages (conditional) random assignment to peer groups within an institution. Examples include roommate assignment in college (Sacerdote, 2001; Stinebrickner and Stinebrickner, 2001, 2006; Zimmerman, 2003; Foster, 2006; Brunello, De Paola and Scoppa, 2010; Griffith and Rask, 2014; Jain and Kapoor, 2015; Garlick, 2018), classroom/section/dorm assignment within institutions (Lyle, 2007; Kang et al., 2007; Graham, 2008; Carrell, Fullerton and West, 2009; De Paola and Scoppa, 2010; Burke and Sass, 2013; Carrell, Sacerdote and West, 2013; Brady, Insler and Rahman, 2017; Feng and Li, 2016; Feld and Zölitz, 2017; Huntington-Klein and Rose, 2018; Garlick, 2018), and study group assignment within classroom (Lu and Anderson, 2015; Hong and Lee, 2017). The second identification strategy uses natural variation in cohort composition. Examples include cross-cohort variation within an institution (Hoxby, 2000; Figlio, 2007); natural shocks or policy-driven changes affecting peer group composition (Angrist and Lang, 2004; Gould, Lavy and Paserman, 2004; Imberman, Kugler and Sacerdote, 2012; Figlio and Özek, 2019); admission cutoffs for schools or classrooms (Pop-Eleches and Urquiola, 2013); and experimental assignment to peer groups (Whitmore, 2005; Duflo, Dupas and Kremer, 2011).<sup>3</sup>

The main findings of this literature are that i) academic peer effects are positive but generally small; ii) the size of academic peer effects depends non-linearly on students' own academic

---

<sup>2</sup>For brevity, we focus on studies of peer effects on academic achievement, but many other studies also document peer effects in e.g. college dropout (Stinebrickner and Stinebrickner, 2001), cheating in school (Carrell, Malmstrom and West, 2008), job search (Marmaros and Sacerdote, 2002), substance abuse (Argys and Rees, 2008; Kremer and Levy, 2008; Card and Giuliano, 2013), crime (Deming, 2011), technology adoption (Oster and Thornton, 2012), consumption (Moretti, 2011), financial decisions (Ahern, Duchin and Shumway, 2014; Bursztyjn et al., 2014) and beliefs (Boisjoly et al., 2006).

<sup>3</sup>It should be clear by now that there are very many studies of peer effects in education — see Sacerdote (2011, 2014) for two excellent reviews. For studies using cross-cohort variation within an institution see also: Hanushek et al. (2003); McEwan (2003); Arcidiacono and Nicholson (2005); Hanushek, Kain and Rivkin (2009); Lavy and Schlosser (2011); Lavy, Paserman and Schlosser (2012); Lavy, Silva and Weinhardt (2012); Kiss (2013); Diette and Uwaifo Oyelere (2014); Kramarz, Machin and Ouazad (2015); Gibbons and Telhaj (2016). For studies using natural- or policy-driven shocks see also: Hoekstra (2009); Clark (2010); Vardardottir (2013); Jackson (2013); Abdulkadiroğlu, Angrist and Pathak (2014); Dobbie and Fryer Jr (2014); Hoekstra, Mouganie and Wang (2018).

ability; and iii) academic peer effects vary in large and seemingly unpredictable ways across settings.

Recent empirical studies have argued that academic peer effects could be largely driven by three types of mechanisms: i) student effort (e.g., Kang et al., 2007; Brunello, De Paola and Scoppa, 2010), ii) group dynamics (e.g., Lavy and Schlosser, 2011; Lavy, Paserman and Schlosser, 2012; Bursztyn and Jensen, 2015; Brady, Insler and Rahman, 2017; Feld and Zölitz, 2017), and iii) teacher effort or school resources (e.g., Duflo, Dupas and Kremer, 2011; Chetty et al., 2011; Hoekstra, Mouganie and Wang, 2018; Todd and Wolpin, 2018). Table 1 lists several of these studies, classifying them by the type of mechanisms they explore.

A separate literature, yet directly relevant for our study, emphasizes the importance of parents as drivers of their children's academic achievement. This literature models academic achievement through an education production function framework—that is, as an output produced from students', parents' and teachers' inputs and governed by well-defined production technologies (such as dynamic or technical complementarities). Recent studies in this literature show, for example, that the benefits of class size reductions are driven by changes in student effort and classroom disruption (Lazear, 2001; Finn, Pannozzo and Achilles, 2003), as well as by changes in teacher behavior (Sapelli and Illanes, 2016) and parental investments (Bonesrønning, 2004; Jacob and Lefgren, 2007; Datar and Mason, 2008; Fredriksson, Öckert and Oosterbeek, 2016). Recent studies estimate structural models of education production functions that include school peers, parents and neighborhoods as inputs (e.g. Agostinelli, 2018; Agostinelli et al., 2020).

In this paper, we estimate the contribution of higher-achieving academic peers to students' test scores and to many educational inputs that may also contribute to improving test scores in their own right. Conceptually, our reduced-form models map the contribution of higher-achieving peers in a linearized version of education production functions. The downside of this approach is that we do not use economic structural information to improve identification. The upside is that our models are transparent in their identifying variation, econometrically tractable, and can easily be used to quantify the share of academic peer effects explained by educational inputs via standard mediation analyses. To take full benefit of this approach we exploit the pairing of Taiwan's policy of random classroom assignment within schools and the rich data in the Taiwan Educational Panel Survey, which we describe in detail in Section 3.

### 3 Institutional Setting and Data

#### 3.1 Education in Taiwan

Figure 1 shows the basic organization of the Taiwanese educational system. Compulsory education in Taiwan starts at primary school, at 6 years old, and ends at the end of junior high school (middle school), around 15 years of age. In practice, however, 95 percent of students continue further onto either General or Vocational Senior High School or Junior College.

**Figure 1:** *The Education System in Taiwan*

*Authors' figure.*

Since the democratization process in Taiwan started in the 1990s, junior high schools have been managed at the municipal level. Students can attend any school they chose but there is preferential school access based on catchment areas within each municipality. The educational curriculum is developed centrally by the Taiwanese Ministry of Education and has no subject specialization until only after junior high school. This unified curriculum is centered around sciences and mathematics and its adoption is often cited as the reason why Taiwanese pupils are consistently placed at the top on international educational rankings (e.g. 4th out of 72 countries in PISA 2015; Law (2004)).

Critical for our identification strategy, since the 1990s municipalities are also mandated by the government to ensure the random assignment of students and homeroom teachers to classrooms within schools. This requirement was formalized by the *Implementation Guideline for Class*

*Assignment of Junior High School Students*, later superseded by Article 12 of the *Primary and Junior High School Act* in 2004.<sup>4</sup> Classroom assignment plays a persistent role in students' education since students typically remain with their assigned classroom and homeroom teacher (or *Dao Shi*) throughout all three years of junior high school.

Students take the National Basic Competence Test at the end of junior high school, which results play a key role for admissions to senior high schools and senior vocational schools. A good placement in these competitive schools, in turn, results in good placements in tertiary education programs, which have high returns in the labor market afterwards. Consequently, students spend time and effort preparing for these exams, and schools regularly organize practice exams and other forms of preparation. Parents are also engaged in their children's preparation, investing in extracurricular tutoring in mathematics, English and sciences largely through cram schools—private extra-curricular institutions preparing for higher education entrance examinations—throughout junior high school or even earlier.

### **3.2 The Taiwan Education Panel Survey**

We use data from the Taiwanese Education Panel Survey (TEPS), a project jointly funded by the Ministry of Education, the National Science Council, and the Academia Sinica. The TEPS is a nationally representative longitudinal survey of the education system in junior high school, senior high school, vocational senior high school, and junior college. The TEPS is a multiple respondent survey, collecting linked information on students, parents, teachers, and school administrators.

We focus on the junior high school sample of the TEPS because the timing of interviews allows us to use measures of student ability and educational inputs upon random assignment to classrooms in Grade 7. The TEPS junior high school sample includes information on more than 20,000 students, their parents, their teachers and their school administrators over two waves. The first wave was collected in early September 2001 at the beginning of students' first year of junior high school, right after their assignment to classrooms. The second wave was collected in 2003, at the beginning of the students' last year of junior high school.<sup>5</sup>

Paired with the mandate of random assignment to classrooms in schools, there are three other key features of TEPS that aid our study. First, its sampling framework allows us to observe a random sample of classmates in each junior high school classroom included in the survey. TEPS follows a stratified nested sampling procedure where first 338 randomly selected junior high schools were sampled (45 percent of all high schools in the country at the time), with

---

<sup>4</sup>Additional details can be found at <http://edu.law.moe.gov.tw/EngLawContent.aspx>.

<sup>5</sup>In contrast, TEPS conducted the first round of interviews of students in general and vocational senior high school, and junior college in their *second* year, one year after assignment to classrooms, barring us from having baseline measures of ability and educational inputs for these samples.

different sampling strata for urban and rural areas, public and private schools, and senior high and vocational schools. In each of these schools an average of three classrooms of first-year students were then randomly sampled. In each of these classrooms, around 15 students were then randomly sampled. The mandated maximum class size at the time was 35 students per class, which implies that observed students in any classroom generally represent a random half of the classroom.<sup>6</sup> This sampling framework is similar to that of the National Longitudinal Study of Adolescent to Adult Health (Add Health), a panel study of a nationally representative sample of middle and high school pupils in the United States. Add Health is unique in collecting friendship ties and in observing multiple cohorts of students in each school, which makes it particularly appealing for peer effect and network research (e.g. Agostinelli, 2018; Elsner and Isphording, 2017; Card and Giuliano, 2013; Bifulco, Fletcher and Ross, 2011; Calvó-Armengol, Patacchini and Zenou, 2009).

Second, and unlike Add Health, students in the TEPS take a standardized test in waves 1 and 2 called the Comprehensive Analytical Ability test. This test measures of students' cognitive ability and analytical reasoning, and it was specifically designed to capture gradual learning over time. There are 75 multiple-choice question in the test, covering general reasoning, mathematics, Chinese and English. These questions were taken from an extensive bank of questions which includes adapted questions from other international standardized tests, as well as questions provided by education and field experts in Taiwan. The Comprehensive Analytical Ability test scores, constructed as the sum of all correct answers, provide excellent measures of academic ability for students and their peers.<sup>7</sup>

Third, TEPS provides a wealth of questions measuring student behavior, attitudes and beliefs in and outside the school environment, parent-child interactions and parental investments, as well as detailed information on teachers and school administrators. Many of these measures have multiple raters, combining questions asked to students, parents, teachers and school administrators. We aggregate all these questions to construct an extensive battery of measures of student, teacher and parent inputs in students' educational production function. This large set of input measures allows us to comprehensively explore potential mechanisms behind academic peer effects.

Based on previous literature, we identified key inputs of students, parents and teachers in the education production function that are potential mediating factors of ability peer effects. For inputs with multiple potential measures, we first identify entire blocks of items in the questionnaires

---

<sup>6</sup>There are other minor sampling restrictions that are irrelevant for our empirical design, we refer the interested reader to TEPS technical reports.

<sup>7</sup>There is some evidence that female students may be disadvantaged compared to male students in multiple-choice measures of cognitive ability (see e.g. Willingham and Cole, 2013). This is not a concern for our study since cognitive ability is measured in a consistent manner throughout the TEPS, and our regression analyses always control for ability at baseline. Nevertheless, we discuss robustness of our results to measurement error in cognitive ability in Section 6.2

of all respondents—e.g. blocks of items related to study effort reported by students, parents and teachers. We then eliminate very low correlates to maximize the informational content of each index and reduce noise. To do this, we compute Spearman correlations between all items under consideration, assess their Cronbach’s alphas, and perform an exploratory factor analysis. Once we narrow down the list of items for a scale, we perform an additional confirmatory factor analysis to validate these items and ensure their item factor loadings have similar magnitudes. Finally, for each of these potential student, teacher and parent mediating factors and in each wave, we construct a summative scale that adds up the answers to each item in the scale. See Appendix A for a detailed explanation and Table A.1 for summary statistics and factor loadings on all scale questions.

We measure student inputs through five scales of student school effort, initiative in class, mental health, truancy, and academic self-efficacy, and three additional dummies for whether students cheat in exams, aspire to go to university, and expect to be able to go to university. We measure parental inputs through four scales of money investments, time investments, parental strictness and parental support, and three additional dummies for whether parents have conflicts with their child, use harsh punishment, and aspire for their child to go to university. Lastly, we measure school and teacher inputs through two scales of student-perceived quality of the school environment and of teacher engagement, and two additional dummy variables for whether teachers reports that the classroom is hard to manage and whether they feel tired of teaching.

Table 2 shows a high-level summary of the academic ability and educational input measures we construct using the TEPS data. For each measure we list the number of items used and the number of unique values each measure takes. Wave 1 measures include many pre-assignment characteristics used in Section 4.2 to provide evidence of random assignment of students to classrooms within schools through a series of tests and methods we explain in the next section.

**Table 2:** *Description of Academic Achievement and Input Measures in TEPS*

Measure	Description	Wave 1		Wave 2	
		Nb of Items (1)	Distinct Values (2)	Nb of Items (3)	Distinct Values (4)
Student inputs					
Test scores	Comprehensive Analytical Ability std. test	75	66	75	59
School effort	Study effort, homework on time (in English, Chinese & math class)	7	23	7	25
Initiative in class	Initiative to ask and answer questions (in English, Chinese & math class)	3	12	3	12
Cheating in exams	Student ever cheats in exams	1	2	1	2
Mental health	Feeling troubled, depressed, suicidal, nervous, unfocused, pressured, irritated, isolated, guilty	6	19	12	22
Truancy	Skipping class, fighting, watching porn, drinking alcohol, stealing, running away from home	6	19	4	10
Academic self-efficacy	Focus, diligence, conscientiousness, initiative, eloquence, organization, cooperation, curiosity	7	22	10	19
University aspirations	Student wants to go to university	1	2	1	2
University expectations	Student expects to be able to go to university	1	2	1	2
Parental investments					
Money investments	Out-of-school tutoring for child: cost, intensity	2	10	3	10
Time investments	Going to bookstores, cultural events with child	2	7	2	11
Parent-child conflict	Student quarrels with father and mother	1	2	1	2
Parental strictness	Father and mother use strict discipline with student	2	7	2	17
Parental support	Father and mother discuss future, listen carefully, worry, give advice, accept unconditionally	8	25	8	7
Harsh parenting	Parents use harsh punishment with student	1	2	1	2
University aspirations	Parents want student to go to university	1	2	1	2
School atmosphere and Teacher engagement					
School environment	Student perception: school study ethos, campus safety, school fairness, staff engagement	5	16	5	16
Classroom management	Teacher assessment: classroom is hard to manage	1	2	1	2
Teacher engagement	Student perception: teacher knows student names, encourages students who work hard, uses several different teaching materials, gives homework, cares about students, reviews questions after exams	6	19	6	36
Teacher tired	Teacher is tired of teaching	1	2	1	2

*Note: This table presents our summative scales, and their associated survey items in each wave of TEPS. Col. (1) and (3) report the number of items used in the construction of each summative scale resp. in Wave 1 and Wave 2, and Col. (2) and (4) indicates the number of distinct values summing each item. For example, the summative scale "School effort" in Wave combines answers to 7 items over 23 distinct values; thus, school effort ranges from 0 to 23.*

## 4 Empirical Strategy

### 4.1 Testing for Random Assignment of Peer Groups

Peer effect studies vary widely in their preferred test of random assignment to peers. In this section, we briefly review and discuss the type of tests used in the literature.

A growing number of peer effects studies have relied on experimental or quasi-experimental data in which students are randomly assigned to peer groups. This literature typically uses three types of test to show that data is consistent with (conditional) random assignment of students to groups. In the first method, researchers regress student  $i$ 's pre-determined characteristics on the classroom leave-out mean—that is, the classroom mean after excluding student  $i$ —of the key regressor of interest. This key regressor is usually a classroom leave-out mean of ability, gender or other pre-determined student behavior (see e.g. Carrell, Sacerdote and West, 2013; Eble and Hu, 2019). A significant coefficient on the classroom leave-out mean indicates that students “treated” with peers differ in that pre-determined characteristic. Because this test mirrors balancing-of-covariates tests in the experimental literature, we refer to them as *balancing tests*.

In the second method, researchers regress student  $i$ 's pre-determined characteristics on classroom leave-out mean of that same characteristic (e.g. Sacerdote, 2001). A positive coefficient on the characteristic classroom leave-out mean indicates that students are sorted into classrooms based on the characteristics tested; hence we call these *sorting tests*. Guryan, Kroft and Notowidigdo (2009) observe that empirically, even under random assignment, coefficients of sorting tests present a small negative bias; they show that this small, mechanical negative correlation between own and peer characteristics seems to disappear when controlling for school-level leave-out-mean of the characteristic. Jochmans (2020) shows that Guryan, Kroft and Notowidigdo (2009)'s empirical correction results in low power for detecting sorting. He further derives analytical expressions for this bias in within-school estimators and proposes a bias-corrected sorting test which solves the power issue of previous sorting tests.

In the third method, researchers run permutation-based (*sorting* or *balancing*) tests (e.g. Carrell, Sacerdote and West, 2013; Lim and Meer, 2017). These tests go as follows. While keeping the core structure of the data (e.g., assignment to schools), researchers simulate what would happen under random assignment to treatment (e.g., to classrooms). Based on this new placebo assignment they then calculate key placebo statistics of interest—sometimes for sorting tests, sometimes for balancing tests, and sometimes for their main results. They repeat this process, say 10,000 times, and each time store their key placebo statistics. Finally, they calculate the proportion of times their placebo statistic has a more extreme value than their actual key statistic. They then calculate the proportion of times the coefficient of the placebo classroom leave-out mean is more extreme than their coefficient of the classroom leave-out mean as observed. This proportion of more extreme occurrences under placebo is a simulation-driven empirical p-value

for a test of random assignment and can be judged by typical standards of statistical significance. These empirical p-values could be calculated for many statistics of interest, including for sorting and balancing tests but also for such tests at the school or even classroom level. When many of these empirical p-values are calculated, researchers can aggregate them into one overarching statistical test using goodness-of-fit tests for the distribution of p-values, which should be standard uniform under random assignment to treatment.

All three methods above are valid ways to produce evidence of quasi-random assignment, yet all methods also have their shortcomings. Neither method naturally corrects for multiple testing when researchers use many pre-determined characteristics in their tests. Using multiple hypotheses testing corrections (e.g. Benjamini and Hochberg, 1995; Romano and Wolf, 2005*a,b*) can, in turn, severely decrease test power. Another approach is to joint-test the significance of all pre-determined characteristics in predicting treatment but these joint tests have a tendency to over-reject, especially when using cluster-robust inference methods (Pei, Pischke and Schwandt, 2019). Permutation tests have the additional problem of being relatively complex to program since researchers are required to keep most of the data structure identical (e.g., assignment to schools, number of classrooms in each school, class size) while still reassigning treatment at random, then correctly recalculate all treatment measures, and ensure that treatment variation is correctly accounted for in all estimates – which is harder with discrete measures of pre-assignment characteristics like gender or race. In addition, goodness-of-fit tests used to aggregate many empirical p-values in permutation tests, such as the Kolmogorov-Smirnoff test, have known power issues.

Given the volume of peer effect studies out there, it is no surprise that in many of them there is evidence of some systematic assignment to peer groups (e.g. Krueger, 1999; Krueger and Whitmore, 2001; Whitmore, 2005; Dee, 2004; Ammermueller and Pischke, 2009; Balsa, Gandelman and Roldán, 2018). When tests of random assignment reject the null that students are randomly assignment to peer groups, researchers have used three types of econometric strategies.

A first approach is to adapt the econometric specification and adjust the interpretation of estimates accordingly (Krueger (1999), for example, estimates intent-to-treat effects rather than treatment effects), or to consider the size of the selection bias when interpreting results (e.g. Dee, 2004). This can be appropriate if the evidence on systematic assignment is weak, quantitatively small, and does not hint at further systematic assignment based on unobservable characteristics that affect student outcomes. The cost, however, is that estimates might be biased if any of these conditions fail.

A second approach is to remove treatment clusters where the data are consistent with some form of systematic assignment to treatment (e.g. Krueger, 1999; Whitmore, 2005; Chetty et al., 2011). This approach is valid if there are clear reasons to believe that random assignment applies to some known treatment clusters but not others, which usually requires intimate knowledge of the institutional background behind the data and the presence of markers of these known clusters.

In complex institutional settings, removing data clusters suspected of systematic assignment to treatment quickly becomes unfeasible and can be very costly in terms of statistical power.

A third approach is to control for pre-assignment characteristics that reveal systematic assignment in the preferred specification, thus relying on mean independence of treatment conditional on these characteristics (e.g. Lavy and Schlosser, 2011; Gong, Lu and Song, 2019). This approach is not costly in terms of power and does not require intimate knowledge of the institutional background, yet it assumes (often implicitly) that controlling for characteristics related to systematic assignment fully accounts for related unobserved characteristics that also determine assignment. Economists are often wary of this assumption. This third approach also comes with other shortcomings. In particular, it assumes that a single parameter function (e.g., linear) in the pre-assignment characteristics is sufficient to account for systematic assignment. This assumption is unlikely to hold if there are several such characteristics or several treatment clusters that differ in their drivers of systematic assignment. Parametrically relaxing this assumption can quickly become costly in terms of power. Perhaps more importantly, controlling for pre-assignment characteristics changes the interpretation of the peer effect estimates, often making them less immediately available for designing better peer group assignment policies. For example, unbiased peer effect estimates that control for parental education can only be used to predict outcomes of reassignment policies that hold parental education constant—a difficult exercise unless student reassignment to classrooms is done explicitly on parental education, which is unlikely to happen in practice.

In sum, there are several ways to test for random assignment of students to peer groups and several ways to deal with an eventual rejection of random assignment. None of the tests are perfect, nor are the solutions. In the next section, we show our main test for random assignment in the TEPS and refer the interested reader to Section 6.1 for the additional tests we run. The case of the TEPS also presents an interesting challenge that combines i) a national mandate of random assignment of students to classrooms within schools, ii) incentives for parents and schools to violate this mandate if they believe that higher-achieving peers affect student outcomes, and iii) unusually rich pre-assignment data to test the outcome of these two clashing institutional features.

Perhaps more importantly, none of the existing tests are designed to identify specific treatment clusters where random assignment is unlikely to hold. In Section 4.2.1 we propose such procedure: a new data-driven method for finding subsamples where quasi-random assignment is credible, which is particularly useful in complex institutional settings such as ours.

## **4.2 Random Assignment to Classrooms in TEPS**

Our identification strategy exploits random assignment of students to classrooms. If random assignment holds, we expect our treatment of interest, classroom leave-out-mean of peer ability, to be as good as randomly assigned to students. Random assignment to *treatment* is the main

identification assumption under which our coefficient estimate yields a causal estimate of the effect of peer ability on subsequent outcomes. Therefore, we first show that our data are generally consistent with random assignment to classrooms, and then show that our treatment is as good as randomly assigned to students.

To show that the data are consistent with random assignment to classrooms within schools, we run sorting tests in the complete TEPS data on standardized test scores and 17 pre-assignment characteristics. We start from the complete sample, to prevent missing values to lead to over-rejecting sorting tests of random assignment. In this complete data, we find evidence of sorting by student ability and by several other student characteristics. We take this as evidence of non-perfect compliance with the mandate of random assignment of students to classrooms within schools across the entire TEPS data (see Appendix Table C.1).

There are many reasons why, in defiance of the national mandate of random assignment, we could find evidence of systematic assignment of students to classrooms. These can range from school principals occasionally catering to some parents' preferences for their child to be assigned to some classrooms, to institutionally allowed "talent" classrooms that pool high-ability student together, to a more concerning blatant disregard for the national mandate across schools. We develop a data-driven procedure that helps us determine the reason behind this seeming violation of random assignment in the data, and identify a sample where random assignment likely holds. We describe the key features of this procedure below, and refer the interested reader to a more complete description in Appendix C.

#### **4.2.1 The Fishing Algorithm**

Since the law in Taiwan has an explicit mandate of random assignment of students to classrooms, we suspect that rejecting the null of sorting tests is most likely driven by few schools that systematically sort students. Unfortunately, our data does not allow us to infer directly which are these schools to exclude them from our analysis.

We therefore designed a sample trimming method, which combines randomization inference, clearly pre-defined selection rules and latent-class modeling. Our Fishing Algorithm is a data-driven approach to identify and exclude the few schools that show evidence inconsistent with conditional random assignment. Since the norm should be random classroom assignment at the school level and since we are interested in ability peer effects, we focus on trimming schools that systematically sort students of similar academic ability into classrooms. This allows to exclude entire treatment clusters (schools) rather than within-cluster treatment cells (e.g., classrooms) which might leave non-random treatment in the remaining cells (i.e., because they are the complement of non-random treated cells). Our method, however, can be easily adapted to trim schools that sort on any observed characteristic in the data, and even on multiple characteristics

at once.<sup>8</sup>

The key five steps of the Fishing Algorithm are the following. First, we construct for each school a measure of *strength of sorting*, indicating how strongly the school sorts students of similar ability into the same classrooms. This measure is akin to a Herfindahl-Hirschman index of ability concentration in classrooms within each school, with larger values indicating stronger ability sorting in classrooms in the school. We call this measure  $H_s$ . Second, for each school we use several permutations of random assignment of students to classrooms within school without replacement and construct, for each simulated classroom assignment, its corresponding simulated index  $H_s^{random}$ . This procedure recovers the distribution of ability concentration in classrooms for each school under the null of random assignment. Third, for each school we compute the share of permutations for which the observed index  $H_s$  in the data was larger than the simulated index  $H_s^{random}$  under the null of random assignment, and call this share  $S_s$ . Under perfect compliance with random assignment, we expect the distribution of  $S$  over schools to be uniform over the  $[0,1]$  interval; if random assignment violated in some schools, we expect more values of  $S_s$  close to 1. Fourth, we estimate the latent probability that each school is a *sorter* (i.e., a school that sorts students into classrooms more strongly than chance would allow). We do this using latent class modelling—an atheoretical data-driven partitioning method that finds observations (e.g., school shares  $S_s$ ) that are likely to be generated by the same stochastic process (e.g., ability-sorted classroom assignment). Using school-level data, we fit a finite mixture model where the outcome is  $S_s$ , the regressors are constants for each latent class, and we include school-level variables that could help identify sorter schools (such as the share of parents who report pushing to get their children assigned to a better classroom). One or more of the latent classes in this model correspond to schools with improbably high  $S_s$ —the sorter schools—and the model itself produces school-level posterior probabilities of each school belonging to this latent *sorter* class. In the fifth and final step, we flag sorter schools based on whether their posterior probability of belonging to the latent sorter class is larger than the combined probabilities of belonging to all other classes. As mentioned above, a more complete description of this Fishing Algorithm can be found in Appendix C, and we provide validation of this procedure using simulated data in Appendix D.<sup>9</sup>

---

<sup>8</sup>Our Fishing Algorithm is also not restricted to finding sorter schools; it can be used to find sorter classes (i.e., classes where students are likely to be sorted based on ability). More generally, it can be adapted to find violations of balancing in any setting with cluster treatment assignment, such as treated villages within countries, or families within neighborhoods. Note also that, in general, our Fishing Algorithm is not equivalent to controlling for observable characteristics to achieve conditional balancing. Our approach combines knowledge of the intended level of treatment assignment (schools) and the nature of the treatment (peers) to non-parametrically identify treatment clusters that likely defy random assignment. Once non-random assignment is detected, we remove entire treatment clusters rather than trying to keep them and account for the non-randomness via controls. Only very stringent selection on observable procedures should be able to capture endogeneity as we do, and even then these would have to apply flexible control functions at the cost of many degrees of freedom and interpretability of estimates.

<sup>9</sup>The question on parental pushiness belongs to a block of questions regarding parental investments in their child's education, including whether parents have or plan on sending their child to study abroad, have changed jobs to be more available for their child, or have relocated to a better educational district to aid their child's education. We

Most schools in the TEPS data show evidence consistent with random assignment, whereas some schools present obvious evidence of sorting (Appendix Figure C.1). As illustrated in Figure 2, our Fishing Algorithm identifies 106 out of the 333 schools in TEPS as sorter schools, which we exclude from our estimation sample. This leaves us with a trimmed sample of 13,685 students in these schools, allocated to 853 classrooms (68 percent of the TEPS data). Our trimmed sample is very similar to the overall TEPS data in terms of all key student and parent characteristics in wave 1, and is also similar to our final estimation sample of 11,029 observations with complete information on student and peer test scores and educational inputs (Appendix Table C.3).

**Figure 2:** Schools Identified as Defying Random Assignment Using the Fishing Algorithm

*This figure shows the school-level distribution of our measure for whether schools sort students into classrooms more strongly than chance would allow, given the school size, number and classroom size and student composition. The probability of being a sorter school is the posterior probability of being in a latent class classified as sorters by us and calculated based on a finite mixture model of school sorting using several school averages of parental characteristics as class predictors. See Appendix C for details.*

An important concern in applying our Fishing Algorithm is over-trimming; that is, to remove schools that by chance look like *sorters* but are not. Our algorithm will unavoidably result in some schools being over-trimmed, and these schools would have contributed useful variation to identify peer effects. With severe over-trimming, peer effects could be less precisely estimated at best, and biased at worst (upwards if e.g., peer effects are strongly driven by positive effects

---

focus on pushy parents because it is the only one of these items that relates directly to classroom assignment and thus our treatment of interest, which could affect our within-school estimates.

of higher-achieving peers on high-achieving students). However, over-trimming is also easily diagnosed in our algorithm; it is revealed by negative and significant post-trimming sorting t-statistics. If negative post-trimming sorting t-statistics occurs, researchers should make efforts to improve the performance of the Fishing Algorithm (by e.g., finding better predictors of sorter schools or exploring different latent lass structures or models). If no improvement can be made, it is important to highlight the over-trimming brought on by the algorithm and cautiously interpret findings accordingly. Fortunately, in our application of the Fishing Algorithm to TEPS we find virtually no evidence of over-trimming.

#### 4.2.2 Sorting and Balancing Tests in our Trimmed Sample

Table 3 presents the results of sorting and balancing tests on the trimmed sample, once we exclude the schools likely to be non-compliant with the mandate of random assignment.<sup>10</sup> Columns (2) and (3) show sorting tests t-statistics, to be compared to standard normal critical values, whereas columns (4) and (5) show coefficients and standard errors of balancing regressions of pre-assignment characteristics on peer ability.

The main endogeneity concern in our estimates is ability sorting of students; that is, that high-ability students are assigned together in the same classroom. This type of sorting is concerning because, if ability is dynamically self-productive as in e.g., Cunha and Heckman (2007), it would bias peer effect estimates upwards. The first row of Table 3 shows that this sorting is not a concern in our trimmed sample.

Another common endogeneity concern is whether students are sorted in productive characteristics other than ability, say parental income. This kind of sorting is tested in the second and third columns, second row and below, of Table 3. Sorting on parental income can introduce bias in peer effects estimates if these characteristics are related to student achievement. Note, however, that if income sorting were related to students' achievement at baseline, this sorting would have already been reflected in the baseline achievement sorting. This still leaves the possibility that parental income has not been productive for student achievement at baseline but might become productive afterwards. If that is the case, income sorting at baseline can still bias peer effects upwards over and above achievement sorting.

Table 3 shows that there is no evidence of sorting on other characteristics in our trimmed sample, especially when using the Jochmans (2020) state-of-the-art test. There is some evidence of sorting on intellectual curiosity and, perhaps more importantly, sorting for students enrolled in gifted arts classrooms and students whose parents report making efforts to get them assigned to

---

<sup>10</sup>For this discussion, it is useful to keep in mind the omitted variable bias formula for our peer effect estimator  $\beta$ :  $\mathbb{E}(\beta|X) - \beta = \gamma\rho$ , where  $\gamma$  is the conditional effect of any omitted factor on student outcomes and  $\rho$  is proportional to the correlation between the omitted factor and our peer achievement leave-out-mean. Evaluating all endogeneity concerns against this formula is an enlightening way to map econometric endogeneity concerns to economic principles.

particular classrooms. Several institutional settings, including TEPS, could allow for this type of sorting to occur over and above achievement sorting.

For student sorting on other characteristics to introduce bias in our peer effect estimates, however, a second necessary condition is for the student characteristic to be related to our peer achievement leave-out-mean measure. The last two columns of Table 3 show these tests. In our trimmed sample, the only potentially concerning characteristic which i) could affect student achievement over and above baseline achievement, ii) students are sorted on at baseline, and iii) is also related to peer achievement at baseline is whether parents made efforts to get their child assigned to a particular classroom. Of all the other characteristics that we test, only family income and family engagement with homework before baseline are related to peer achievement, and they are negatively related at that. This last finding rather suggests a potential slight over-trimming in our Fishing Algorithm (since pre-trimming these relationships were, if anything, positive; see Appendix Table C.1). Regardless, in our main specifications we include the corresponding controls for household income, family engagement with homework, gifted art classroom assignment, and parents' pushiness to get child assigned to a particular classroom, which we jointly refer to as balancing controls. These balancing controls are not crucial for our empirical design, nor do they affect any of our main results.<sup>11</sup>

Overall, our Fishing Algorithm is an effective way to identify schools that systematically assign student to classrooms in our data. In the schools identified by the algorithm as balanced we find no substantive evidence of systematic assignment, and we will keep this trimmed sample as our estimation sample throughout our main analyses. In Section 6 we also show the results of a battery of additional sorting tests, discuss in detail other ways to identify our estimates, explore the issues of sample selectivity, and compare our trimmed sample with the initial TEPS sample.

---

<sup>11</sup> Also, note that due to the power in our data, we detect small differences in balancing tests that would have likely gone unnoticed in other designs. Our ex-post Minimum Detectable Effects (MDEs) for our balancing tests are as small as 2.2 percentage points in the chance of being female, and less than 1 percentage point in the likelihood of having a migrant background. For comparison, the MDEs of balancing tests are 17 percent of a standard deviation in math test scores in the STAR data (Dee, 2004), and 25 percentage points for being female and 10 percentage points for migrant in the Add Health data (Bifulco et al., 2014).

**Table 3: Balancing and Sorting Tests on the TEPS Trimmed Sample**

Treatment Variable:	Students	Sorting tests (t-statistic)		Balancing tests	
		Peer outcome leave-out mean	Peer ability leave-out-mean [std]	Coef.	Std. err.
	(1)	Guryan et al. (2009) (2)	Jochmans (2020) (3)	(4)	(5)
<i>Pre-assignment characteristics:</i>					
Student test scores [std]	13,685	-0.2	0.1		
Female student	13,685	2.1	-0.2	0.008	(0.011)
Student born before 1989	13,611	-0.8	0.6	-0.005	(0.010)
Household income > NT\$100k/mo.	13,454	-0.7	-0.3	-0.019***	(0.007)
College-educated parent(s)	13,084	-0.8	0.8	0.001	(0.009)
Parent(s) work in government	13,023	1.4	0.0	0.010	(0.007)
Ethnic minority parent(s)	13,081	2.2	1.4	-0.004	(0.009)
<i>Since primary school:</i>					
Student always prioritized studies	13,593	-1.7	0.8	-0.010	(0.009)
Student always reviews lessons	13,583	-0.2	1.7	0.003	(0.008)
Student likes new things	13,554	1.5	<b>2.4</b>	-0.001	(0.011)
<i>During primary school:</i>					
Student was truant	13,489	1.6	-0.7	0.000	(0.011)
Student had mental health issues	13,486	-0.7	0.2	-0.004	(0.010)
Student quarreled with parents	13,502	-1.5	-1.2	-0.001	(0.009)
<i>Before junior high school:</i>					
Had private tutoring	13,525	0.3	1.4	0.004	(0.012)
Family help with homework	13,013	1.2	0.8	-0.020**	(0.008)
Student enrolled in gifted academic class	13,554	-1.2	1.8	0.013	(0.008)
Student enrolled in arts gifted class	13,554	<b>2.2</b>	<b>2.9</b>	-0.013	(0.015)
Parents made efforts to place student in better class	13,508	<b>2.2</b>	<b>3.2</b>	0.035***	(0.010)

*Note: This table presents the results of balancing and sorting tests in our trimmed sample of 232 schools and 850 classrooms. All estimators include school fixed effects. The reference distribution for the Guryan, Kroft and Notowidigdo (2009) and the Jochmans (2020) sorting statistics is the standard normal. The last column reports cluster-robust standard errors at the classroom level. \*\*\*, \*\* and \* mark estimates statistically different from zero at the 90, 95 and 99 percent confidence level.*

## 5 Main Results

### 5.1 Academic Peer Effects on Test Scores

Now that we have established a sample where conditional random assignment of students to classrooms holds, we go on to establish the existence of academic peer effects.

**Figure 3:** *The Effect of Higher-Achieving Peers Test Scores on Students' own Test Scores in Wave 2*

This figure reports estimates of regressing standardized student test scores in wave 2 on standardized average peer test scores in wave 1 in our sample containing 232 schools, 850 classes, and up to 11,029 students. Rows present results of models with different sets of control variables. The Baseline model includes wave 1 student test scores and school fixed effects. Balancing controls include household income, family engagement with homework, gifted art class assignment, and parents' efforts to get child assigned to a particular classroom. W1 inputs include standardized scales of student inputs (school effort, initiative in class, truancy, academic self-efficacy, and mental health), parent inputs (investment in private tutoring, time investments, parental strictness and parental support), school and teacher inputs (school environment and teacher engagement). Horizontal bars show the 99%, 95% and 90% confidence intervals for each estimate, based on standard errors clustered at the classroom level. Estimates in this figure are also shown in Appendix Table B.1.

In its most basic form, we test for the existence of academic peer effects in our setting by regressing students' standardized test scores in wave 2,  $TestScores_{ics2}$ , on the standardized classroom leave-out mean of test scores in wave 1,  $\overline{TestScores_{ics1}^{-i}}$ , our measure of average peer test scores. To this simplest specification we add school fixed effects and students' own test scores in wave 1. We do not include homeroom teacher fixed effects since these teachers are also randomly assigned to classrooms so they cannot confound our peer effect estimates (see Section 3.1 and Chang, Cobb-Clark and Salamanca (2020)). Moreover we do not observe the same homeroom teacher across multiple classrooms so our estimates would not be econometrically

identified in a teacher fixed effect model. We do consider specifications with and without the additional balancing controls (household income, family engagement with homework, gifted art classroom assignment, and parents' pushiness to get child assigned to a particular classroom) and standardized scales of student inputs (school effort, initiative in class, truancy, academic self-efficacy, and mental health), parent inputs (investment in private tutoring, time investments, parental strictness and parental support), school and teacher inputs (school environment and teacher engagement). We do this to assess the extent to which these covariates could capture omitted variable bias in our peer effect estimates. We cluster standard errors at the classroom level.

Figure 3 shows strong positive peer effects in our setting. It further shows that including balancing controls or wave 1 inputs does not qualitatively change our estimates, though it does slightly increase precision. This estimate stability is a reassuring result which provides strong evidence of no omitted variable bias in our estimates, especially given the wide range of controls included in our educational input measures.

Our preferred specification is on the last row of Figure 3, highlighted in bold. This specification controls for school fixed effects and student wave 1 test scores, as well as all wave 1 educational inputs and our four balancing covariates. It therefore identifies academic peer effects within the Todd and Wolpin (2003) cumulative value-added specifications; holding constant past outputs and educational inputs. This will prove important in the following sections. Our preferred estimates can be re-expressed as:

$$TestScores_{ics2} = 0.054 \overline{TestScores_{ics1}^{-i}} + 0.562 TestScores_{ics1} + \hat{\theta}' Controls_{ics1} + \hat{\mu}_s \quad (1)$$

(0.017) (0.009)

where  $Controls_{ics1}$  includes balancing controls and wave 1 educational inputs.

These estimates imply that having one standard deviation higher average peer test scores in wave 1 increase own test scores by 5.2 percent of a standard deviation in wave 2. Comparing effect sizes in this literature is quite difficult; differences in standardized effect sizes across studies could capture true differences in responses to peer ability but could also reflect differences in standard deviations in peer achievement and student outcomes across settings. Assuming these standard deviations are comparable across studies, our peer effects are also similar (e.g. Imberman, Kugler and Sacerdote, 2012; Brunello, De Paola and Scoppa, 2010; Booij, Leuven and Oosterbeek, 2017). Compared to studies where students are randomly assigned to peer groups, our estimates are around the median of estimate. Yet our estimated effect measures the impact of two years' worth of exposure to classroom peers, which represents a strong dose compare to most comparable studies, thus our effect could also be seen as relatively small.<sup>12</sup>

---

<sup>12</sup>The combination of partial classroom sampling and random assignment of students to classes in TEPS implies

To give this number more perspective, our estimated effect of a 1SD increase in average peer scores is about a tenth of the estimated effect of a 1SD increase in students' own lagged test scores. Our peer effect estimate is about half the marginal effect of having at least one college-educated parent, and about a sixth of the unconditional test score gap between children of two-parent households and single-parent households.

Another way of sizing the impact of higher-achieving peers is through the lens of socioeconomic inequality. Due largely to school sorting, the peers of poor students (with household monthly incomes under NT\$20,000, corresponding to the poorest 10 percent in the sample) have 68 percent of a standard deviation lower scores than the peers of rich students (with household monthly incomes over NT\$100,000, corresponding to the top 15 percent). The rich-poor test score gap in wave 2 test scores is 1.1 standard deviations. Putting these two numbers together, our linear peer effects imply that 3.5 percent of the rich-poor gap in standardized test scores can be explained by the richer students' access to higher-achieving peers.

## 5.2 Academic Peer Effects on Educational Inputs

In this section, we estimate the impact of higher-achieving academic peers on nineteen educational inputs in order to explain how academic peer effects work. We estimate variations of Equation (1) using our measures of educational inputs in wave 2 as outcomes. Figure 4 shows the effect of a 1SD increase in average peer test scores on wave 2 educational inputs in our estimation sample. Each row shows the effect of peer test scores on a different educational input. We show the unconditional mean of each outcome in square brackets to give context to these estimates. Navy blue estimates show effects student inputs, maroon estimates show effects on parent inputs, and teal estimates show effects on school and teacher inputs.

A 1SD increase in average peer test scores decreases students' school effort in wave 2 by 5.2 percent of a standard deviation. While these effects are a priori surprising, they are difficult to benchmark against previous findings. Many studies have hypothesized study effort to be a key mechanism through which peer effects operate, yet a handful of them provide estimates of effort responses to high-achieving peers. The few studies that do find mixed evidence (Feld and Zölitz, 2017; Mehta, Stinebrickner and Stinebrickner, 2019; Fang and Wan, 2020).

The negative effect of higher-achieving peers on student effort might seem surprising. One possible explanation is that exposure to high achieving peers could constitute a form of relative performance feedback, which can affect effort decisions (Azmat and Iriberry, 2010). Intuitively, students start with a prior belief about their ability relative to their peers', and those exposed to high-achieving peers update their belief downwards. This has a flow-on effect on effort, which can be positive if students have competitive or rank-preferences (e.g. Azmat et al., 2019; van

---

that these and all other peer effect estimates in our main results might be biased downwards (Sojourner, 2013). We discuss the source of this bias, and present and interpret corrected estimates, in Section 6.2.3.

Lent and Souverijn, 2020; Clark et al., 2020) or negative if students become discouraged by the tournament-like stakes in the classroom (Bedard and Fischer, 2019). Our negative effects on effort in the TEPS data suggests the discouragement effect is the larger of the two.

**Figure 4:** *The Effect of Higher-Achieving Peer Test Scores on Educational Inputs in Wave 2*

This figure reports estimates of regressing educational input measures in wave 2 on standardized average peer test scores in wave 1 in our sample containing 232 schools, 850 classes, and up to 11,029 students. Rows present results of models with different educational inputs as outcomes. Unconditional means of each outcome are shown in square brackets, and [std] marks outcomes that have been standardized to have a mean of zero and a standard deviation of one. All models control for school fixed effects, student test scores in wave 1, balancing controls, and educational inputs in wave 1. Student, parent, school and teacher inputs are shown in navy blue, maroon, and teal. Horizontal bars show the 99%, 95% and 90% confidence intervals for each estimate, based on standard errors clustered at the classroom level. Estimates in this figure are also shown in Appendix Table B.2.

A 1SD increase in average peer test scores also increases students' aspirations to go to university by 1.6 percentage points, and their expectations of actually going to university by 2 percentage points. These seem like small effects, corresponding to around 3-5 percent of their respective unconditional means, but become more sizeable when compared to the effect of other known shifters of aspirations. One could compare them, for example, to the 8.5 percent increase in parents' higher education aspirations for girls from opening access to male-dominated professions in India (Beaman et al., 2012), the 5.2 percent increase in educational aspirations of cast-priming in high-casts in India as well (Mukherjee, 2015), or the precisely-estimated null effect of university information on educational aspirations of Colombian students (Bonilla-Mejía, Bottan and Ham, 2019).

A 1SD increase in peer test scores also increases parents' time investment by 8.1 percent of a

standard deviation. Our time investment measure in TEPS focuses in dinner time spent with parents, yet our estimated peer effect could be compared to half of the impact of having one student more in one's classroom on parents' likelihood of helping the child with homework in Fredriksson, Öckert and Oosterbeek (2016), or with a fifth of the effect of a child attending a marginally worse school in Pop-Eleches and Urquiola (2013). 1SD higher-achieving classroom peers also increases parental strictness by 3.6 percent of a standard deviation, a small effect that has no benchmark in the peer effects literature.

Finally, Figure 4 also shows that we cannot detect effects of higher-achieving peers on many educational inputs that have previously been considered as key potential mechanisms behind peer effects, such as student initiative in the classroom, classroom disruption and the quality of peer interactions in the classroom (e.g. Booi, Leuven and Oosterbeek, 2017; Feld and Zölitz, 2017). We estimate null effects on all measures of parental investment or parenting behavior other than parental time investments. This finding is important because while we find no parental behavioral responses to classroom peer ability, previous studies have shown evidence of parental behavioral responses to other types of public investments such as school admissions, classroom size, and teacher qualifications. Lastly, we also find precisely estimated null effects on mechanisms that others have found potentially relevant including on students' perception about their school environment (e.g. Feld and Zölitz, 2017), and on teacher engagement, classroom management and tiredness (Lazear, 2001; Duflo, Dupas and Kremer, 2011; Golsteyn, Non and Zölitz, Forth.).

Importantly, our null effects on most of these mechanisms are precisely estimated. Between all our estimates, the largest standard error for a standardized educational input is 0.026. A standard ex-post Minimum Detectable Effect (MDEs) size calculation with 95 percent confidence and 80 percent power implies that we could have detected effects as small as 7.3 percent of a standard deviation for outcomes such as initiative in class or teacher engagement. A 7.3 percent of a standard deviation in an outcome is a relatively small detectable effect; close to 10 percent of the gender gap in effort (women pay more effort than men), 18 percent of the difference between private tutoring investments of top-income parents and the rest, or 9 percent of the difference between the time investments of two-person and single-parent households.

Overall, we show that higher-achieving peers decrease student effort, increase student aspirations and expectations to attend university, an increase in parental time investments and parental strictness. We can make sense of the first two, seemingly contradicting, results in the lens of existing theories of performance under uncertainty; they could be consistent with exposure to higher achieving peers as a form of relative performance feedback. The sign of these estimates is in line with the theoretical model and recent field evidence of Azmat et al. (2019). The latter result on time investments provide new insights on the relatively thin evidence base on parents' behavioral responses to school inputs. Our effects suggest that parents complement school inputs (i.e., better school peers) by increasing their own time investment. This collides with evidence that parents tend to treat school inputs and own time investments and parental strictness as

substitutes (Pop-Eleches and Urquiola, 2013; Fredriksson, Öckert and Oosterbeek, 2016) but is consistent with other evidence from Taiwan that showing that parents complement teacher qualifications with financial investments of their own (Chang, Cobb-Clark and Salamanca, 2020).

More relevant is that — depending on the productivity of these educational inputs for student achievement — these input responses could all be legitimate mechanisms for explaining our 5.2 percent of a standard deviation effect of higher-achieving peers on test scores. In the next section, we calculate how much of our estimated academic peer effect can be explained by these mechanisms.

### 5.3 Mediation of Academic Peer Effects

We are now able to formally ask how much of the 5.2 percent effect of higher-achieving peers on students’ test scores can be explained by their intermediate impact on educational inputs. To do this we follow the decomposition in Gelbach (2016), which we adapt to our setting in order to use only within-school variation by modifying the `b1x2` Stata package.

This decomposition calculates the total mediated effect ( $ME$ ) of educational inputs on peer effects:

$$ME = \sum_k ME_k = \sum_k \underbrace{\frac{\partial Ed.Inputs_{ics2}^k}{\partial TestScores_{ics1}^i}}_{(A)} \times \underbrace{\frac{\partial TestScore_{ics2}}{\partial Ed.Inputs_{ics2}^k}}_{(B)} \quad (2)$$

where  $Ed.Inputs_{ics2}^k$  stands for educational input in our set of inputs. The terms (A) are the causal effects of higher-achieving peers in wave 1 on educational inputs in wave 2 as shown in Figure 4. The only remaining pieces for the calculation of  $ME$  are therefore the terms which are the partial returns (i.e., holding other inputs constant) to each of the educational inputs on student scores in wave 2.

There is no ideal experiment for estimating (B), not even by independently and randomly varying each educational input over a period of two years and then estimating their causal impact on student test scores. The reason, as expressed by Todd and Wolpin (2003), is that such experiments would identify “policy parameters”—effect identified out of variation not subject to choices of parents or schools but exogenously induced—rather than “production function” parameters. Policy parameters are identified by variation in inputs exogenously pressed onto people, rather than by naturally-occurring variation through people’s investment decisions across the population (see e.g. Imai, Tingley and Yamamoto, 2013; Keele, Tingley and Yamamoto, 2015). Thus, policy parameters answer many important questions but they do not recover returns to inputs, so their use is limited in a mediation analysis as described by Equation (2).

Todd and Wolpin (2003) argue for using (cumulative) value-added models to estimate the (B) term of Equation (2). Todd and Wolpin (2007) and Fiorini and Keane (2014), among others,

discuss these models in detail and show that they can identify the returns to educational inputs under relatively weak conditions, and we find ourselves in an ideal scenario for estimating these models. This is because in our setting we i) always use within-school variation which accounts for unobserved school-level heterogeneity, ii) can control for standardized test scores in wave 1, iii) can control for a myriad of educational inputs in wave 1, and iv) only need to estimate returns over a two-year period. For all these reasons, we estimate the terms (B) as the  $\hat{\beta}_k$  from the within-school cumulative value-added model:

$$TestScore_{ics2} = \sum_{k=1}^K \beta_k Ed.Inputs_{ics2}^k + \delta Covariates_{ics1} + \gamma_s + v_{ics2} \quad (3)$$

where  $Covariates_{ics1}$  includes student test scores, average peer test scores, and all other educational inputs in wave 1. To the extent that our school fixed effects account for school-level unobserved heterogeneity  $\gamma_s$  and extensive set of high-quality covariates account for endogeneity in observable educational inputs, Equation (3) will identify unbiased estimates of the average partial return to each of the  $K$  educational input in our data.<sup>13</sup>

Figure 5 presents within-school cumulative value-added estimates of the total and partial average returns of educational input in wave 2. Total effects are return parameters estimated one input at the time. Partial effects are the return parameters estimates  $\hat{\beta}_k$  obtained from Equation (3) with the complete set of  $K$  inputs include as regressors together. In other words, they are the returns of each educational input  $k$  holding constant all other  $K - 1$  inputs. We rescale test scores and all continuous inputs in wave 2 so that each value can easily be interpreted as the return of a one standard deviation increase in standard deviations of scores. The circles show the total returns of each input, and the bars show the partial effect of each input with their corresponding 95 percent confidence interval.

We obtain precise estimates of the average partial returns to all educational inputs. The first row in Figure 5, for example, shows that a 1SD increase in school effort between waves 1 and 2 carries an average return of 9.3 percent of a standard deviation in test scores in wave 2. There are also positive returns to students' initiative in class, university aspirations and expectations, as well as parental money investment in the form of private tutoring, parental support and university aspirations for their child. There is evidence of negative returns to students' academic self-efficacy, and parental strictness and harshness. The differences between total and partial average

---

<sup>13</sup>School fixed effects are theoretically not necessary for identifying our value-added parameters, yet we include them to easily map our academic peer effects on inputs onto a mediation analysis using shared modelling assumptions. Our value-added parameters do not change when we use classroom fixed effects, student fixed effects, or remove fixed effects altogether. Attenuation due to classical measurement error could also affect our value-added estimates, yet this would not meaningfully change our conclusions since i) most of our input measures combine several items, which reduces measurement error substantially, and ii) our measures tend to have excellent inter-item consistency and high Cronbach alphas, which suggest little measurement error left in them. Back-of-the-envelope models with reasonable levels of attenuation assumed for our value-added models support these conclusions.

**Figure 5: Returns to Educational Inputs from Cumulative Value-Added Models**

This figure reports coefficient estimates of regressing student test scores in wave 2 on educational inputs in wave 2 in our estimation sample containing 232 schools, 850 classes, and up to 11,029 students. Rows present coefficients of different regressors; Unconditional means of each input are shown in square brackets and [std] marks inputs that have been standardized to have a mean of zero and a standard deviation of one; circles show total effects (one input at the time) and bars represent partial effects (all inputs jointly). All models control for school fixed effects, student test scores, average peer test scores, and educational inputs in wave 1. Student, parent, school and teacher inputs are shown in navy blue, maroon, and teal. Spikes show 95% confidence intervals on partial effects based on standard errors clustered at the classroom level. These results are also available in Appendix Table B.3.

returns reflect the fact that many of these inputs are correlated.<sup>14</sup>

Figure 6 puts together the results from Figures 3 to 5 to produce estimates of the mediated effect of peer effects by our measured educational inputs, as per Equation (2). This figure reports the mediated effects based on a Gelbach (2016) decomposition of our academic peer effect estimate using only within-school variation in our complete sample, and allowing errors to be correlated across the scores and input equations. The bar in green shows that our mechanisms explain a negative and statistically but not economically significant amount of our estimated peer effect—which means that the effect of higher-achieving peers on these inputs and their estimated return jointly make it *harder*, not easier, to explain the academic peer effects. Jointly, all our ed-

<sup>14</sup>The  $R^2$  in our cumulative value added model is 0.71 which suggests we explain a substantial amount of the variation in wave 2 test scores with our data. Our measured inputs contribute the vast majority of the explanatory power; the same model without school fixed effects has only a slightly lower  $R^2$  of 0.69. There is also not much scope for within-classroom variation to contribute additional explanatory power since adding classroom fixed effects only increases the  $R^2$  to 0.74.

educational inputs explain only -0.8 percent of a standard deviation of the 5.2 percent of a standard deviation academic peer effect. This negative mediation is chiefly driven by the negative effects of higher-achieving peers on effort combined with the large and positive estimate of the returns to effort on academic achievement. None of the other inputs we consider has a statistically or economically significant mediating effect.

**Figure 6: Academic Peer Effects Mediated by Educational Inputs**

*This figure reports the mediated effects based on a Gelbach (2016) decomposition of our academic peer effect estimate using only within-school variation in our estimation sample containing 232 schools, 850 classrooms, and up to 11,029 students. These estimates are produced using a modified version of the `b1x2` Stata package. Rows present the mediated effect of different educational inputs in wave 2. All models control for school fixed effects, student test scores, average peer test scores, and educational inputs in wave 1. The total mediated effect is shown in green, and student, parent, school and teacher inputs are shown in navy blue, maroon, and teal. p-values shown are based on standard errors clustered at the classroom level. These results are also available in Appendix Table B.4.*

Overall, the results in this section show that, in spite of having precise estimates of i) academic peer effects and of ii) the effects of higher-achieving peers on educational inputs, which could potentially act as mechanisms for these peer effects, our potential mechanisms explain practically nothing of peer effects. These new results show the difficulties of learning about the mechanisms that drive social interaction effects and suggest that the prevailing microeconomic approach to exploring these mechanisms can be of limited use. Puzzling results such as these open a number of questions and can prove to be a knowledge base to build on, as long as its foundations are solid. Precisely because of this, in the next section we show that our main results and conclusions are robust to a myriad of specification checks and potential concerns. In particular, section 6.4 shows that these results on the absence of mediation are not hiding

heterogeneity in the sense that we find little heterogeneity in the effect of high-achieving peers on scores and inputs across different subgroups of students.

## **6 Sensitivity Analyses**

In this section, we discuss the sensitivity of our results along four dimensions: i) robustness to changes in our identification strategy; ii) robustness to the effects of measurement error in our data; iii) robustness of our inference to different constructions of standard errors; and iv) robustness of our conclusions on the mediation analyses to the presence of heterogeneous peer effects.

### **6.1 Robustness of Identification Strategy**

Here, we first provide additional evidence of random assignment of students to classrooms within schools in our trimmed sample using permutation-based sorting tests, and using non-parametric sorting tests. Many of these tests have become standard in the empirical peer effects literature. We then exploit the richness of our data—in particular the fact that we observe many pre-assignment characteristics of students, parents and teachers—to show that proportional selection on unobservable characteristics is very unlikely to be driving our results.

#### **6.1.1 Permutation-Based Sorting Tests**

In the empirical peer effects literature, permutation-based tests of random assignment of students to peer groups have become very popular. These tests compared the actual student group composition in the data to counterfactual compositions simulated under the null of random assignment, as described in Section 3.3.2. As an additional check for random assignment in our data, we estimate permutation-based sorting tests akin to those in e.g., Carrell and West (2010); Lim and Meer (2017, 2020) in our trimmed sample.

For these tests, we simulate 10,000 classrooms under the null of random assignment of students to classrooms within schools. We do so by randomly drawing sampled students with replacement and keeping the core structure of the data—respecting students’ assignment to schools, and number and size of classrooms within each school. We then calculate the mean of our key pre-treatment characteristics in each of the 10,000 synthetic classrooms. Finally, for each classroom, we count the times the synthetic classroom mean of each characteristic was more extreme than the actual classroom mean, relative to the schools mean. The share of times this happens corresponds to the classroom-level empirical p-value of a test of random assignment of students to classrooms within schools based on that characteristic. Appendix Table B.5 shows these permutation-based empirical p-values for each key pre-determined characteristic separately. Under random assignment, the shares in the second through fourth column should be close to the nominal rejection rates of 0.10, 0.05 and 0.01 in most or all rows. The evidence in

this table strongly supports the idea of random assignment to classrooms within schools in our trimmed sample.

### **6.1.2 Non-Parametric Sorting Test**

As implemented, balancing tests and sorting tests all have one important shortcoming: their linearity. Balancing tests, for example, assess whether female students are assigned to higher-achieving peers. Sorting tests try to capture whether female students end up in classrooms with other female students. But these tests do not truly test for what random assignment would imply: whether classrooms systematically differ in these pre-assignment characteristics in any way. In other words, these tests do not test non-parametrically for systematic assignment of students to classrooms. A few studies do use this non-parametric sorting test (Ammermueller and Pischke, 2009; Sojourner, 2013; Feld and Zölitz, 2017).

We implement this test in the following steps. First, we estimate school-by-school regressions of each pre-assignment characteristic on a set of classroom dummies. Second, we jointly test the statistical significance of these classroom dummies and collect the p-values of these tests. We end up with a set of 2,790 p-values; one for each of the 227 schools in our sample and each of our key 18 pre-assignment characteristics. We then note that, under the null of random assignment of classrooms to schools, these p-values should be uniformly distributed. Therefore, as a third step, we check whether more than ten, five and one percent of the school-level p-values fall under the nominal values 0.10, 0.05 and 0.01 for each characteristic.

Appendix Table B.6 shows empirical p-value distributions for each characteristic separately. Consistent with our tests in Section 4.2, these results also show some evidence of minor sorting based on intellectual curiosity, gifted arts classroom enrolment, and parents pushing for assignment to particular classrooms. Overall, however, these tests provide yet again evidence in strong support of random assignment to classrooms within schools in our trimmed sample.

### **6.1.3 Different thresholds for our Fishing algorithm**

An important and somewhat arbitrary decision in implementing our Fishing Algorithm is deciding when to classify any particular school as not compliant with the mandate of random assignment. Recall from Section 4.2.1 that we do so based on how each school's probability to belong to the latent class of sorters—the latent sorter probability, for short. Our intuitive thumb rule is: a school is a sorter if its latent sorter probability is larger than all other latent class probabilities combined. However, this is not the only way to classify such schools. Another approach is to pick a fixed probability threshold and consider any school with a latent sorter probability above that threshold as a sorter.

In Appendix Table B.7 we show how all our main results on academic peer effects change had we implemented this fixed threshold approach at different levels, ranging from 0.5 (relatively strict, removing all schools that are “more likely than not” to be sorters) to 1 (very relaxed, effec-

tively removing only schools for which  $S_s$  is equal to 1 too). The bottom of the table shows that the sorting statistic of Jochmans (2020) grows monotonically with the threshold, as expected, and starts rejecting the null of no sorting for thresholds of 0.7 and above. For thresholds below 0.7, we find consistent academic peer effects on test scores of around 5 percent of a standard deviation, as well as consistent negative effects on student effort and positive effects on students' university expectations, and time with parents. We find weaker and less consistent evidence of positive effects on students' university aspirations, parental support, and teacher engagement, and negative effects on conflict with parents. In general for thresholds 0.7 and below all coefficients are very stable and compare well to our main effects. For thresholds above 0.7, where sorting tests fail, we tend to find larger academic peer effects on test scores, smaller effects in magnitude on student effort and time with parents, and larger effects in magnitude for parental support, parents' university aspirations, and class management. Most of these differences are consistent with stronger ability sorting into classrooms for these schools. Overall, Appendix Table B.7 shows that our results are not overly sensitive to which threshold we use in our fishing algorithm as long as the resulting estimation sample passes Jochman's sorting test.

#### **6.1.4 Proportional Selection on Unobservable to Observable Characteristics**

Our trimmed sample is chosen in a data-driven way that ensures that key pre- assignment characteristics are unrelated to average peer test scores. This identification strategy relies on our ability to find data that reflects a clean quasi-experiment in classroom allocation, yet systematically excludes entire schools from our sample, which might lead to sample selection issues. Still, we ask ourselves whether the few observable characteristics that remain correlated to higher-ability peers could present reasonable concerns about unobserved heterogeneity. This calls for an analysis of proportional selection on observable characteristics, as discussed in Altonji, Elder and Taber (2005) and Oster (2019). The two conditions for this analysis to make sense are i) that our observable characteristics for these analyses are a random sample of all determinants of student achievement, and ii) that the number of observed and unobserved determinants of student achievement are large and neither element is dominating. Along the argument lines of Altonji, Elder and Taber (2005), we assume that the TEPS fulfils both conditions.

We implement this analysis by calculating the  $\delta$  statistic from Oster (2019); the share of proportional selection needed to explain away the entire peer effect we estimate. Values of  $\delta > 1$  imply that the selection on unobservable characteristics would need to be at least as large as the selection on observable characteristics to explain away the entire peer effect estimate, which, given the data and data context, is an unreasonable assumption. A  $\delta < 1$  implies that the omitted variable bias from unobservable variables positively correlated with the observable variables included would bias the peer effects *away from zero*, not towards, and should therefore not be concerning as confounders. In this type of analysis, thus, finding values of  $\delta$  between zero and one is worrisome, and could indicate a potential concern for unobserved selection affecting results. The observables we use for these analyses are extensive: they include our balancing con-

trols (household income, family engagement with homework, gifted art classroom assignment, and parents' pushiness to get child assigned to a particular classroom) and our standardized measures of student, parent, school and teacher educational inputs in wave 1. Assuming that selection on unobservable characteristics occurs in proportion to the selection on this set of variables implies, by exclusion, that school fixed effects and students' own test scores in wave 1 — a priori essential for our identification strategy and standard in the literature — cannot inform the proportional selection analyses. We also use a hypothetical maximum R-Squared value of 1.3 times the R-Squared of the unrestricted model, which is the standard choice for these analyses.

Appendix Table B.8 shows Oster's  $\delta$  for all our main estimates estimating using the `psacalc` Stata command. For nearly all our estimates, Oster's  $\delta$  is negative which implies that proportionally selection on unobserved confounders are unlikely to explain our effects. The one exception is the  $\delta$  of 0.10 for the effect of higher-achieving peers on parental investments in tutoring, which is anyway insignificantly different from zero so none of our conclusions change following the results of this analysis. Overall, we conclude that proportional selection on unobservable variables cannot explain away any of our findings.

## 6.2 Robustness to Measurement Error and Classroom Sampling

We now turn our focus to the measurement error in our data. We show that our main estimates i) are robust to using different measures of student and peer academic ability, ii) are not attenuated by measurement error in average peer test scores, and iii) are not biased by the fact that we do not observe whole classrooms.

### 6.2.1 Main Results with Alternative Measures of Ability

Our main results use the TEPS scores in the comprehensive ability test. As discussed in Section 3.2, this test was designed by TEPS team and uses 75 multiple-choice question to measure of students' cognitive ability and analytical reasoning. However, after a series of factor analyses and after estimating 3-parameter Item Response Theory (IRT) models, the TEPS team could also identify two highly correlated but distinct subcomponents measuring analytical ability and mathematical ability based on disjoint subsets of test questions. The IRT models were also used to produce the standardized Bayesian posterior means of the three components identifiable in the test—the general ability component and the analytical ability and mathematical ability subcomponents.<sup>15</sup>

Appendix Table B.9 shows that our main results are robust to using the analytical and mathematical subcomponents of the comprehensive ability test scores as measures of student and peer

---

<sup>15</sup>See <http://www.teps.sinica.edu.tw/description/TestingReport2004-2-10.pdf> (in Mandarin) for a description of these analyses.

ability (columns (1) and (2)). Our main results are also robust to using the Bayesian posterior means of these components, arguably a more precise and efficient measure of ability (columns (3) through (5)).

### 6.2.2 Correction for Classical Measurement Error in Peer Ability

Even in excellent measures of student and peer ability, such as the well-designed standardized test scores in TEPS, there will still be some measurement error. Under random assignment and with classical measurement error (i.e., independent of all covariates and of true ability), this measurement error will attenuate our peer effect estimates (Sojourner, 2013; Feld and Zölitz, 2017; Angrist, 2014). We can address this attenuation bias in two similar ways. Noting that the analytical and mathematical subcomponents of test scores are measured with disjoint sets of questions, we can use average peer test scores using one subcomponent as an instrument for average peer test scores using the other in an instrumental variable (IV) estimator. See e.g., (Salamanca et al., Forth.) for a similar approach to account for measurement error in personality traits. This approach would eliminate attenuation bias from classical measurement error under two assumptions: i) that both subcomponents have a strong common element of overall ability, and ii) that measurement error in test questions is uncorrelated across subcomponents. The first assumption is well supported by our data and by the TEPS team factor and IRT analyses. The second assumption is stronger; if it does not hold it would result in some attenuation bias left in the IV estimate.

Appendix Table B.10 shows that, although less precisely estimated due to the usual efficiency loss from instrumental variable models, the IV point estimates are near-identical to our main results (columns (1) and (2)). We thus view this as evidence of little attenuation bias due to classical measurement error in our estimates.

One potential problem with the estimators above is that the IV estimates need to be interpreted as academic peer effects in *analytical* and *mathematical* ability, rather than in *comprehensive* ability. We address this problem by constructing a “mixed IV” estimator. In this estimator, we first construct an ability measure that, for each student, is randomly defined as either the analytical subcomponent score or the mathematical subcomponent score with equal probability. This ability measure is therefore an equal-weighted average of the analytical and mathematical subcomponents and can be interpreted as measuring general ability. We call this our ‘mixed ability’ measure. We also construct an ability instrument that is defined by the same random process to be the subcomponent that was not assigned as ability. For example, if for student ability is measured as the analytical subcomponent score, then the ability instrument is defined as the mathematical subcomponent score. We call this our ‘mixed ability instrument’. Under the same assumptions above, an IV estimate that instruments our mixed ability with our mixed ability instrument also corrects for attenuation bias while identifying academic peer effects using general ability, rather than analytical or mathematical ability. We show that this new estimator produces very similar results to our main peer effect on test scores (Appendix Table B.10 , column (3)).

It also produces slightly larger estimated magnitudes of the effect of higher-achieving peers on study effort and students' university aspiration and expectations, and similar estimates for the effect on parental time investments (Appendix Table B.11). Back-of-the-envelope calculations show that these slightly larger estimates do not change our conclusions on the mediated effects of higher-achieving peers. We thus conclude that measurement error does not alter any of our main findings.

### **6.2.3 Sojourner (2013) Correction for Incomplete Classroom Sampling**

Many empirical peer effect studies, including ours, has incomplete classroom data which results in incomplete sampling of students' peer group. Sojourner (2013) shows that this issue can result in bias in peer effect estimates that is similar to classical attenuation bias under random assignment, and much more difficult to sign and quantify under non-random assignment. He also proposes a correction for this bias that relies on i) weighting estimates by the share of peers sampled and ii) controlling for these shares at the school level. Often these last controls are multicollinear with the weighted peer measures, so he also suggests less restrictive estimators that control for the share of peers sampled within predetermined school clusters. We implement both methods in our data to evaluate the extent of this bias in our main results. The left-most column on the table implements Sojourner's preferred correction which can lead to substantial loss of power because it heavily restricts the identifying variation used by the estimator. The second through sixth columns implement specifications which trade off more power for less bias reduction, from left to right.

Appendix Table B.12 shows substantially larger effects of higher-achieving peers on student test scores, ranging from 8.9 to 13.3 percent of a standard deviation which nevertheless remain within the range of estimates found in previous studies, especially considering that peers here have had two years to work their effect on student achievement. These corrections also yield proportionally larger effects on students' university aspirations and expectations and parental time investments, which is all consistent with Sojourner's findings and with the data originating from conditional random assignment to classrooms within schools. The analyses do not reveal other effects of higher-ability peers. Moreover, since the attenuation in all our estimates is roughly proportional, our conclusions about mediated peer effects remains unchanged. This suggests that not observing complete classrooms in our data could lead to understating the importance of academic peer effects, but does not affect our (in)ability to explain their mechanisms.<sup>16</sup>

---

<sup>16</sup>There are other potential issues with incomplete classroom sampling, especially if our peer effects varied with classroom or school size, if the classroom sampling rate were correlated with our regressors, or if our Fishing Algorithm were selecting schools with different average sampling rates. Fortunately, none of these occur in our data.

### 6.3 Randomization Inference and Multiple Hypothesis Testing

Having established the robustness of our point estimates of peer effects, in this subsection we show that our inference on these effects is robust to i) constructing standard errors based on recent randomization inference techniques and ii) to accounting for multiple hypotheses testing in our standard error calculations.

We first reassess inference on our main results using the randomization-t procedure from Young (2019). Our analyses benefit from this procedure because of the potential influence of a few high-leverage students, classrooms or schools, and we want to ensure that our inference is robust to this occurrence. We also want to use inference that does not make strong assumption on the structure of error terms given the complexity of the TEPS sampling design and peer treatment. Other benefits of randomization inference, such as i) correcting for few treatment clusters or ii) issues of joint testing are less important for this study, because i) we observe several classrooms per school, and ii) each regression has one treatment effect of interest.

We construct randomization-t based empirical p-values via a very similar simulation procedure to the one used for permutation tests. The key difference is that, in each simulation, we capture the t-statistics of interest—the coefficient of the key variable of interest divided by its cluster-robust standard error—and construct empirical p-values based the share of occurrences where simulated t-statistics are more extreme than our actual t-statistic of interest. We use 10,000 simulations of random assignment to classroom within schools to produce randomization-t empirical p-values for our main results. Appendix Table B.13 shows that when using randomization-t inference p-values for conducting inference, our main conclusions on the effects of higher-achieving peers hold at the 5% significance level for student achievement and parental time investments, and at the 10% significance level for student university aspirations and expectations.

In a second analysis, we adjust our inference for multiple hypotheses testing: the problem that the chance of falsely rejecting a correct null hypothesis increases with the number of tests performed. We adjust for this by implementing the Romano-Wolf multiple hypothesis correction (Romano and Wolf, 2005*a,b*) using the `rwolf` Stata command (Clarke, Romano and Wolf, 2019). This procedure ensures that the familywise error rate—the probability of committing at least one Type I error across a set of hypotheses tested—does not exceed its predetermined significance. We consider all our main results to be part of the same family of tests. Appendix Table B.13 shows that our main conclusions on the effect of higher-achieving peers on student achievement and on parental time investment hold at the 10% significance level, but our evidence on students' university aspirations and expectations now appear not to be statistically significant.

Overall, with these different inference methods we still find strong evidence of academic peer effects in our data but somewhat weaker evidence of significant effects on educational inputs. This reinforces our conclusions of no mediated effects for academic peer effects.

## 6.4 Heterogeneous Peer and Mediated Effects

Finally, we explore the sensitivity of our mediation analyses. Our chief concern here is the possibility that our lack of meaningful mediation can occur not because educational inputs cannot explain academic peer effects, but rather as the result of heterogeneity peer effects across subgroups. Heterogeneity can occur in two forms: firstly, academic peer effects could vary widely across subgroups—a result found in several studies across ability (Carrell, Fullerton and West, 2009), gender (Whitmore, 2005; Lavy and Schlosser, 2011), race (Hoxby, 2000; Hoxby and Weingarth, 2005), but secondly and perhaps most importantly, the drivers of peer effects for each subgroup could also widely differ, as suggested by (Brady, Insler and Rahman, 2017). For example, higher-achieving peers could improve test scores of low-ability students because they reduce the amount of classroom disruption (see e.g. Lavy, Paserman and Schlosser, 2012) and improve test scores of high-ability students because they increase effort. Yet we might be unable to detect enough mediation via truancy and effort on the average academic peer effect. This form of heterogeneity would wrongly lead us to conclude that truancy and effort cannot explain at least part of academic peer effects. One way to assess whether this particular type of heterogeneity is a likely explanation for our findings is to estimate the heterogeneity of peer effects and their mediation via educational inputs across various subgroups.

There are countless dimensions to explore heterogeneity in academic peer effects in our data. Based on existing heterogeneous effects in the academic peer literature, and on a broader literature on the sociodemographic predictors of student test scores, we explore peer effect and mediation heterogeneity across: student ability, gender, household income, parental education, public vs private schooling, and teacher experience. Appendix Table B.14 shows that, by and large, there is little subgroup heterogeneity in our estimated academic peer effects and their mediation. Academic peer effects are slightly larger at the top and middle of the student ability distribution, with highly experienced teachers, and in private schools, yet are the same across student gender, household income, and parental education. More importantly, our inputs can still mediate either small or negative parts of these academic peer effect for any one of these subgroups. Altogether, we show strong evidence of little heterogeneity in academic peer effects and in mediated effects.

We also consider the possibility that our mediation is affected heterogeneity of the value-added parameters across the peer ability distribution. This could occur if higher-achieving peers change e.g., the productivity of some teaching practices (Aucejo et al., 2020). There is evidence of similar heterogeneity in our data: having higher-achieving peers increases returns to student effort and initiative in class, decreases returns to private tutoring and time spent with parents, and increases the penalty for being in a hard-to-manage classroom (see Appendix Table B.15). This heterogeneity is broadly consistent with higher-achieving peers being complements to some student and teacher investments in class and substitutes to some parental investments at home in the education production function. However, note that for the two inputs where we find both significant academic peer effects and significant heterogeneity (school effort and time

with parents), higher-achieving peers would increase the return to effort and decrease the return to time with parents. Since academic peer effects are negative for effort and positive for time with parents, this together adds up to *even less* mediation when we allow for heterogeneity in our value-added estimates.

Based on these results we conclude that subgroup heterogeneity is not a likely explanation for the fact that our many educational inputs do not mediate academic peer effects.

## 7 Conclusions

We estimate the effect of being randomly assigned to classrooms with higher-achieving peers on students' standardized test scores two years later, and on 19 other intermediate outcomes of students, their parents, and their teachers. We conduct a formal mediation analysis of academic peer effects to explore several potential mechanisms, one of the first ones of its kind in a field with over twenty years of research and hundreds of articles. Our study thus gives the most comprehensive view of how much academic peer effects are explained by changes in educational investments in a setting with a credible identification strategy.

For producing these results, we use data in a setting with a well-documented country-wide mandate of random assignment of students to classrooms within schools. The data, however, shows that this random assignment was likely not upheld everywhere, which is not entirely surprising: we can think of legal and illegal ways in which sorting can still occur—for example, via allowed “talent” classrooms in schools, or due to principals sorting students into classrooms in defiance of the mandate. Similar violations to national mandates are common in similar settings (e.g. Gong, Lu and Song, 2019; Eble and Hu, 2019). We develop a data-driven procedure to remove schools likely to be defying the mandate of random assignment from our estimation sample and show that data in this trimmed sample is strongly consistent with random assignment. This Fishing Algorithm can be used to improve quasi-experimental designs in settings where random assignment to peers is suspected to be violated in some, but not all, assignment groups. It can more generally be used in any setting where researchers suspect imperfect compliance of (quasi-)experimental treatment assignment in some clusters.

One might wonder if our results can really tell us something about academic peer effects in other settings. Yet data from the Trends in International Mathematics and Science Study (TIMSS) in 1999 shows that Taiwan's educational setting is altogether not that different from many others across the world (Appendix Table B.16). And while students in Taiwan do spend relatively more days per year in school, and have lower rates of absenteeism, none of these differences helps us explain why we still find positive academic peer effects of similar size to many other studies, yet no evidence of mediation.<sup>17</sup> Moreover, Taiwan is comparable to other countries—

---

<sup>17</sup>What some of these differences could explain, however, is why we find negative effects of higher-achieving peers

especially in the Australasia and Pacific region—in most other key dimensions including class size, student-teacher ratios, daily study hours, dropout rates, or class disruption.

Since our academic peer effects remain largely unexplained, it could be tempting to conclude that academic peer effects are unexplainable by current methods. Instead, we see at least two avenues for future research.

The first avenue is to keep on striving to find data on potential mechanisms. It is true that most potential mechanisms for academic peer effects proposed in previous studies feature in one way or another in the TEPS (see Appendix Table 1), many of them more carefully measured than ever before. Two notable exceptions are: direct learning from peers and detailed teaching practices. Measuring direct peer learning (e.g., discussing tasks and coordinate among group mates) requires data on peer-to-peer interactions which is difficult to gather, yet could indeed be the missing explanation for academic peer effects (e.g., Garlick, 2018; Zárate, 2020; Kimbrough, McGee and Shigeoka, Forth.). Detailed teaching practices (e.g., how teachers pair students for group work or the amount of material covered in each lesson ) are also hard to measure yet some of them are strongly related to student achievement gains (e.g., Kane et al., 2011) and one can easily think of ways in which teachers adapt their teaching style to classroom ability.

The second avenue is to further explore heterogeneity in the value-added of educational inputs. Imagine a world in which academic peer effects exist in every school, but they occur via different channels. In one school higher-achieving peers increase effort while in another they decrease class disruption, and in yet another they increase parental engagement. Such dramatic differences in the mechanisms of peer effects become increasingly likely with school segregation and specialization. In such a world, we would find positive peer effects across schools and no mediation on average, just as we do. Such cancellation of mechanisms is not unheard of; it is documented in Bursztyn, Egorov and Jensen (e.g., 2019) where they show that making effort observable can either increase or decrease student effort depending on the social norm in the school. One could explore this hypothesis in the academic peer effect context via school-specific academic peer effects and value-added functions. Unfortunately the data requirements for such exercise are enormous: we would need rich data on many schools with many classrooms, where random assignment holds and with a longitudinal dimension to it. We simply do not know of a dataset with these features, not even the TEPS.

Our results also get us closer to using peer effects to confidently inform and design classroom assignment policies. A pervasive concern with systematic assignment policies is that their benefits might come with unmeasured cost on, e.g. classroom disruption, increasing stress and deteriorating mental health for both students and teachers, and higher effort to keep up with one's higher-achieving peers. Our study shows that many of these concerns are unfounded. If

---

on student effort. Taiwanese students might be exerting so much effort already that the demoralizing effect of these peers takes hold easier.

anything, higher-achieving peers seem to improve classroom atmosphere, an effect which has been found in e.g. Feld and Zölitz (2017). In the absence of measurable costs, our results suggest that higher-achieving peers could be an effective way to increase student achievement, even if we do not quite know how they work yet.

## Appendix A Construction of Standardized Scales in TEPS

We summarize the wealth of data available in TEPS into standardized summary indices using commonly used data reduction methods. We proceed as following:

1. Compute Spearman correlation of all potential variables in the factor to construct: eliminate very low correlates; Run preliminary PCA on remaining variables
2. Count number of missing values by individual across variables
3. Standardize each variable, construct preliminary index as row-mean across standardized variables
4. Cut preliminary index into deciles: construct bins of similar input
5. For each variable, construct median within index decile among people used for imputation. If missing item and less than 1/3 missing, replace missing value by median within index decile.
6. Re-run PCA now using variables with imputed values, to check visually that factor with and without imputed values have same distribution

In the long table below, we report for each index we use:

- the items used, and the corresponding respondent (Teacher, Student or Parents),
- the initial number of observations for each of these items separately,
- PCA factor loadings before and after imputation,
- the number of observations for the factor before and after imputation,
- the eigenvalue of the first and second factors before and after imputation,

Factor for which no imputation has been performed are indicated by blanks for factor loadings after imputation, observations after imputation and eigenvalue of first factor after imputation.

**Table A.1:** Construction of Standardized Scales of Educational Inputs in TEPS

Scale and Survey items used in scale	Obs. (1)	Resp. (2)	Factor loadings	
			Original (3)	Imputed (4)
<i>Effort wave 1</i>				
Chinese teacher's assessment of student effort in class	18,508	T	0.75	0.76
English teacher's assessment of student effort in class	17,961	T	0.73	0.75
Math teacher's assessment of student effort in class	18,126	T	0.71	0.72
Dao Shi report student always completes homework on time	18,571	T	0.62	0.63
Chinese teacher's report always completes homework on time	18,627	T	0.70	0.71
English teacher's report always completes homework on time	18,233	T	0.67	0.68
Math teacher's report always completes homework on time	18,394	T	0.65	0.66
Factor observations			16,004	19,231
First factor eigenvalue			3.35	3.46
Second factor eigenvalue			0.16	0.14
<i>Effort wave 2</i>				
Chinese teacher's assessment of student effort in class	17,120	T	0.78	0.79
English teacher's assessment of student effort in class	16,509	T	0.76	0.77
Math teacher's assessment of student effort in class	16,612	T	0.74	0.76
Dao Shi report student always completes homework on time	17,161	T	0.71	0.72
Chinese teacher's report always completes homework on time	17,107	T	0.68	0.69
English teacher's report always completes homework on time	16,657	T	0.63	0.65
Math teacher's report always completes homework on time	16,698	T	0.62	0.64
Factor observations			14,251	17,950
First factor eigenvalue			3.48	3.62
Second factor eigenvalue			0.13	0.11
<i>Mental health wave 1</i>				
How often feeling down or frustrated	19,781	S	0.74	0.74
How often feeling troubled, worried	19,877	S	0.74	0.73
How often want to scream or smash something	19,854	S	0.64	0.64
How often feeling body shaking, unable to focus	19,839	S	0.68	0.68
How often feeling lonely	19,793	S	0.76	0.76
How often hopeless	19,856	S	0.75	0.75
Factor observations			19,493	19,934
First factor eigenvalue			3.09	3.09
Second factor eigenvalue			0.33	0.32
<i>Mental health wave 2</i>				
How often feeling down or frustrated	18,716	S	0.71	0.71
How often want to scream or smash something	18,712	S	0.67	0.67
How often feeling body shaking, unable to focus	18,695	S	0.62	0.62
How often feeling lonely	18,676	S	0.64	0.64
How often feeling that you have bad fortune	18,658	S	0.59	0.59
How often feeling easily irritated by others	18,682	S	0.62	0.62
How often guilty, regret over some things	18,654	S	0.58	0.58
Factor observations			18,355	18,782
First factor eigenvalue			2.82	2.83
Second factor eigenvalue			0.24	0.24

*Note:* This table presents detailed factor loadings and number of observations used in the construction of our summative scales as imputation procedure. Col. (1) reports the initial number of complete observations available, Col. (2) indicates whether teachers (T), parents (P) or students (S) respond to each item, Cols. (3) and (4) report factor loadings on the first factor respectively before and after imputation. See Appendix Appendix A for details about our imputation procedure.

**Table A.1:** Construction of standardized scales of educational inputs in the TEPS data (continued)

Scale and Survey items used in scale	Obs. (1)	Resp. (2)	Factor loadings	
			Original (3)	Imputed (4)
<i>Truancy wave 1</i>				
How often cutting or skipping classes	19,846	S	0.70	0.70
How often physical fights or quarrels with teachers	19,790	S	0.61	0.6
How often watching porn	19,867	S	0.65	0.64
How often substance abuse (tobacco, alcohol, drugs)	19,865	S	0.74	0.73
How often running away from home	19,880	S	0.73	0.73
How often stealing or destroying others' property	19,862	S	0.68	0.67
Factor observations			19,614	19,929
First factor eigenvalue			2.83	2.77
Second factor eigenvalue			-0.002	-0.01
<i>Truancy wave 2</i>				
How often cutting or skipping classes	18,718	S	0.51	0.52
How often physical fights or quarrels with teachers	18,737	S	0.59	0.59
How often watching porn	18,729	S	0.42	0.42
Factor observations			18,611	18,799
First factor eigenvalue			0.78	0.79
Second factor eigenvalue			-0.07	-0.07
<i>Self-efficacy wave 1</i>				
I am good at presentations or expressing my points of view	19,749	S	0.65	0.65
I am good at coordinating with other people in a group	19,800	S	0.68	0.68
I can plan things well no matter how trivial they are	19,810	S	0.74	0.73
I cooperate with everyone very well	19,798	S	0.62	0.62
I always come up with solutions to problems	19,758	S	0.57	0.57
I have always reviewed what I learn since elementary school	19,847	S	0.59	0.59
I always try to figure out answers whenever have questions	19,808	S	0.59	0.59
Factor observations			19,346	19,909
First factor eigenvalue			2.83	2.83
Second factor eigenvalue			0.17	0.16
<i>Self-efficacy wave 2</i>				
I am good at presentations or expressing my points of view	18,686	S	0.54	0.53
I am good at coordinating with other people in a group	18,744	S	0.58	0.58
I can plan things well no matter how trivial they are	18,731	S	0.65	0.64
I cooperate with everyone very well	18,709	S	0.55	0.54
I always come up with solutions to problems	18,708	S	0.62	0.62
My friends think of me as a person who always has lots of ideas	18,606	S	0.54	0.54
Factor observations			18,384	18,795
First factor eigenvalue			2.02	2.01
Second factor eigenvalue			0.05	0.05

*Note:* This table presents detailed factor loadings and number of observations used in the construction of our summative scales as imputation procedure. Col. (1) reports the initial number of complete observations available, Col. (2) indicates whether teachers (T), parents (P) or students (S) respond to each item, Cols. (3) and (4) report factor loadings on the first factor respectively before and after imputation. See Appendix Appendix A for details about our imputation procedure.

**Table A.1:** Construction of standardized scales of educational inputs in the TEPS data (continued)

Scale and Survey items used in scale	Obs. (1)	Resp. (2)	Factor loadings	
			Original (3)	Imputed (4)
<i>Initiative in class wave 1</i>				
Chinese teacher report student initiative to participate in class	18,635	T	0.52	0.53
English teacher report student initiative to participate in class	18,307	T	0.52	0.54
Math teacher report student initiative to participate in class	18,367	T	0.52	0.54
Factor observations			17112	19219
First factor eigenvalue			0.81	0.86
Second factor eigenvalue			-0.16	-0.16
<i>Initiative in class wave 2</i>				
Chinese teacher report student initiative to participate in class	17,161	T	0.58	0.61
English teacher report student initiative to participate in class	16,787	T	0.61	0.64
Math teacher report student initiative to participate in class	16,698	T	0.59	0.62
Factor observations			15,426	17,791
First factor eigenvalue			1.06	1.16
Second factor eigenvalue			-0.16	-0.16
<i>Money wave 1</i>				
Hours per week spent on tutoring in/outside school	19,851	P	0.60	0.60
Amount paid for this child's tutoring classes	19,710	P	0.60	0.60
Factor observations			19,573	19,988
First factor eigenvalue			0.71	0.73
Second factor eigenvalue			-0.25	-0.25
<i>Money wave 2</i>				
Hours per week spent on tutoring outside school	18,747	P	0.78	0.78
Monthly expenditures this semester for this child's tutoring	18,755	P	0.78	0.78
Factor observations			18,586	18,916
First factor eigenvalue			1.21	1.22
Second factor eigenvalue			-0.21	-0.20
<i>Time wave 1</i>				
How often parents go to bookstores or expos with child	19,750	P	0.53	0.53
How often parents go to concerts or performances with child	19,750	P	0.53	0.53
Factor observations			19,743	19,757
First factor eigenvalue			0.55	0.55
Second factor eigenvalue			-0.24	-0.24
<i>Time wave 2</i>				
Weekly number of dinners with the child	18,783	P	0.44	0.45
Spouse: Weekly number of dinners with the child	18,493	P	0.44	0.45
Factor observations			18,457	18,819
First factor eigenvalue			0.39	0.41
Second factor eigenvalue			-0.21	-0.21

*Note:* This table presents detailed factor loadings and number of observations used in the construction of our summative scales as imputation procedure. Col. (1) reports the initial number of complete observations available, Col. (2) indicates whether teachers (T), parents (P) or students (S) respond to each item, Cols. (3) and (4) report factor loadings on the first factor respectively before and after imputation. See Appendix Appendix A for details about our imputation procedure.

**Table A.1:** Construction of standardized scales of educational inputs in the TEPS data (continued)

Scale and Survey items used in scale	Obs. (1)	Resp. (2)	Factor loadings	
			Original (3)	Imputed (4)
<i>Parent strictness wave 1</i>				
My father is strict	19,851	S	0.51	0.51
My mother is strict	19,842	S	0.51	0.51
Factor observations			19,739	19,928
First factor eigenvalue			0.52	0.53
Second factor eigenvalue			-0.23	-0.24
<i>Parent strictness wave 2</i>				
How many of your parents set strict rules for your daily routine?	18,828	S	0.61	0.61
How many of your parents set strict rules about spending money?	18,819	S	0.54	0.54
How many of your parents set strict rules about demeanor?	18,806	S	0.63	0.63
How many of your parents set strict rules about health habits?	18,731	S	0.60	0.60
How many of your parents set strict rules about making friends?	18,821	S	0.57	0.57
How many of your parents uses guilt and emotional blackmail?	18,821	S	0.51	0.51
How many of your parents does not allow you to argue with them?	18,816	S	0.50	0.50
How many of your parents discipline you very strictly?	18,809	S	0.53	0.53
Factor observations			18,648	18,831
First factor eigenvalue			2.54	2.55
Second factor eigenvalue			0.15	0.15
<i>Parent emotional support wave 1</i>				
My father discusses student's future study and career	19,854	S	0.46	0.46
My father discusses my feelings and thoughts	19,764	S	0.59	0.58
My mother discusses student's future study and career	19,822	S	0.49	0.50
My mother discusses my feelings and thoughts	19,816	S	0.64	0.64
My father accepts me as I am	18,993	S	0.49	0.51
My mother accepts me as I am	19,370	S	0.49	0.49
My family provides strong emotional support	19,652	S	0.53	0.54
In my family, we discuss together important decisions	19,528	S	0.56	0.57
Factor observations			17,729	19,973
First factor eigenvalue			2.28	2.33
Second factor eigenvalue			0.56	0.52
<i>Parent emotional support wave 2</i>				
My parents pay attention to my ideas and thoughts	18,816	S	0.66	0.66
I seek my parents' help when I encounter difficulties	18,811	S	0.67	0.67
My parents accept me as I am	18,799	S	0.62	0.62
Factor observations			18,769	18,827
First factor eigenvalue			1.27	1.27
Second factor eigenvalue			-0.15	-0.15

Note: This table presents detailed factor loadings and number of observations used in the construction of our summative scales as imputation procedure. Col. (1) reports the initial number of complete observations available, Col. (2) indicates whether teachers (T), parents (P) or students (S) respond to each item, Cols. (3) and (4) report factor loadings on the first factor respectively before and after imputation. See Appendix Appendix A for details about our imputation procedure.

**Table A.1:** Construction of standardized scales of educational inputs in the TEPS data (continued)

Scale and Survey items used in scale	Obs. (1)	Resp. (2)	Factor loadings	
			Original (3)	Imputed (4)
<i>School environment wave 1</i>				
My school is an interesting place	19,513	S	0.47	0.48
My school is fair in terms of rewards and grading	19,557	S	0.54	0.55
The campus of my school is safe	19,567	S	0.63	0.63
My school cares about their students	19,481	S	0.71	0.71
My school has a great atmosphere for learning	19,456	S	0.64	0.65
Factor observations			18,701	19,903
First factor eigenvalue			1.83	1.86
Second factor eigenvalue			-0.006	-0.013
<i>School environment wave 2</i>				
My school's requirements on students are quite reasonable	18,614	S	0.39	0.39
My school is fair in terms of rewards and grading	18,741	S	0.46	0.46
The campus of my school is safe	18,709	S	0.56	0.56
My school cares about their students	18,340	S	0.62	0.62
My school has a great atmosphere for learning	18,690	S	0.52	0.52
Factor observations			18,053	18,814
First factor eigenvalue			1.33	1.34
Second factor eigenvalue			0.015	0.013
<i>Teacher engagement in class wave 1</i>				
How many of my teachers know the name of every student	19,865	S	0.38	0.39
How many teachers encourage student when they study hard	19,780	S	0.48	0.48
How many teachers use different teaching methods/materials	19,846	S	0.55	0.55
How many teachers give homework to increase students' chance to practice	19,836	S	0.48	0.49
How many teachers ask reasons when students fail homework	19,812	S	0.46	0.48
How many teachers give a review after every exam	19,604	S	0.48	0.49
Factor observations			19,210	19,953
First factor eigenvalue			1.35	1.4
Second factor eigenvalue			0.11	0.11
<i>Teacher engagement in class wave 2</i>				
How many teachers talk about people skills in class	18,795	S	0.70	0.70
How many teachers often discuss life goals, do career advice	18,784	S	0.73	0.73
How many teachers often recommend books, encourage reading	18,783	S	0.62	0.62
How many teachers often use real life and practical examples	18,772	S	0.62	0.62
How many teachers take free time to help students with personal issues	18,795	S	0.53	0.53
How many teachers often use guilt or emotional blackmail	18,784	S	0.45	0.45
How many teachers praise me when I study hard	18,744	S	0.53	0.53
Factor observations			18,590	18,820
First factor eigenvalue			2.56	2.56
Second factor eigenvalue			0.17	0.17

*Note:* This table presents detailed factor loadings and number of observations used in the construction of our summative scales as imputation procedure. Col. (1) reports the initial number of complete observations available, Col. (2) indicates whether teachers (T), parents (P) or students (S) respond to each item, Cols. (3) and (4) report factor loadings on the first factor respectively before and after imputation. See Appendix Appendix A for details about our imputation procedure.

## Appendix B Additional Tables

**Table B.1:** *The Effect of Peer Test Scores on Students' Own Test Scores in Wave 2*

	Outcome: Student test scores in wave 2 [std]			
	(1)	(2)	(3)	(4)
Peer test scores [std]	0.041*** (0.016)	0.047*** (0.016)	0.052*** (0.016)	0.052*** (0.016)
Own test scores [std]	0.737*** (0.007)	0.733*** (0.007)	0.589*** (0.009)	0.585*** (0.009)
R2	0.65	0.64	0.68	0.68
School FE	Y	Y	Y	Y
Balancing controls		Y		Y
W1 inputs			Y	Y
Schools	232	232	232	232
Classes	872	872	850	850
Students	13,086	12,173	11,702	11,029

*Note:* This table reports estimates of regressing standardized student test scores in wave 2 on standardized average peer test scores in wave 1 in our sample containing 232 schools, 850 classrooms, and up to 11,029 students. Balancing controls include household income, family engagement with homework, gifted art classroom assignment, and parents' efforts to get child assigned to a particular classroom. W1 inputs include standardized scales of student inputs (school effort, initiative in class, truancy, academic self-efficacy, and mental health), parent inputs (investment in private tutoring, time investments, parental strictness and parental support), school and teacher inputs (school environment and teacher engagement). Standard errors clustered at the classroom level in parentheses. Estimates in this figure are also shown in Figure 3.

**Table B.2:** *The Effect of Peer Test Scores on Educational Inputs in Wave 2*

Treatment variable:	Peer test scores [std]				
	Coef. (1)	Std. err. (2)	R2 (3)	Classrooms (4)	Students (5)
<i>Outcomes: educational inputs</i>					
School effort [std]	-0.052**	(0.024)	0.56	849	10659
Initiative in class [std]	-0.015	(0.024)	0.46	849	10558
Truancy [std]	0.009	(0.021)	0.18	850	11113
Cheated on exams [.48]	0.015	(0.013)	0.12	850	11078
Academic self-efficacy [std]	-0.017	(0.021)	0.15	850	11113
Mental health [std]	-0.030	(0.019)	0.16	850	11103

Teacher engagement [std]	0.022	(0.023)	0.11	850	11129
Teacher tired of teaching [.49]	-0.042	(0.031)	0.31	836	10527

*Note:* This table reports estimates of regressing educational input measures in wave 2 on standardized average peer test scores in wave 1 in our sample containing 232 schools, 850 classrooms, and up to 11,164 students. Rows present results of models with different educational inputs as outcomes. Unconditional means of each outcome are shown in square brackets, and [std] marks outcomes that have been standardized to have a mean of zero and a standard deviation of one. All models control for school fixed effects, student test scores in wave 1, balancing controls, and educational inputs in wave 1. Standard errors clustered at the classroom level in parentheses. Estimates in this table are also shown in Figure 4.

**Table B.3:** Returns to Educational Inputs from Cumulative Value-Added Models

	Outcome: Student test scores in wave 2 [std]

R2			0.71	
Schools			232	
Classes			850	
Students			10,490	

*Note:* This table reports coefficient estimates of regressing student test scores in wave 2 on educational inputs in wave 2 in our estimation sample containing 232 schools, up to 850 classrooms, and up to 11,029 students. Rows present coefficients of different regressors. Unconditional means of each input are shown in square brackets and [std] marks inputs that have been standardized to have a mean of zero and a standard deviation of one. Total effects are estimated one input at the time, whereas partial effects are estimates of all inputs jointly. All models control for school fixed effects, student test scores, average peer test scores, and educational inputs in wave 1. Standard errors clustered at the classroom level in parentheses. These results are also available in Figure 5.

**Table B.4:** *Academic Peer Effect Mediated by Educational Inputs*

	Student test scores in wave 2 [std]	
	Coef. Est. (1)	Std. err. (2)
<i>Total mediated effect</i>	−0.008	(0.005)
<i>Mediated effect by:</i>		
School effort	−0.006***	(0.002)
Initiative in class	−0.001	(0.003)
Truancy	−0.000	(0.000)
Cheated on exams	−0.000	(0.000)
Academic self-efficacy	0.001	(0.001)
Mental health	0.000	(0.000)
University aspirations	0.000	(0.000)
University expectations	0.001	(0.001)
Private tutoring	0.000	(0.000)
Time with parents	−0.000	(0.000)
Conflict with parents	−0.000	(0.000)
Parental strictness	−0.001	(0.001)
Parental support	0.000	(0.000)
Harsh parenting	−0.000	(0.000)
Parent uni. Aspirations	−0.000	(0.001)
School environment	−0.000	(0.000)
Classroom hard to manage	0.000	(0.001)
Teacher engagement	0.000	(0.000)
Teacher tired of teaching	−0.001	(0.001)

*Note:* This table reports the mediated effects based on Gelbach's (2016) decomposition of our academic peer effect estimate using only within-school variation in our estimation sample containing 232 schools, up to 850 classrooms, and up to 11,029 students. These estimates are produced using a modified version of the `b1x2` Stata package. Rows present the mediated effect of different educational inputs in wave 2. All models control for school fixed effects, student test scores, average peer test scores, and educational inputs in wave 1. Standard errors clustered at the classroom level in parentheses. These results are also available in Figure 6.

**Table B.5:** *Permutation-Based Classroom-Level Sorting Tests in Estimation Sample*

	Classrooms (1)	Share of classes with empirical p-val. under			Avg. p-value (5)
		0.10 (2)	0.05 (3)	0.01 (4)	
<i>Pre-assignment characteristics:</i>					
Student test scores	853	0.10	0.06	0.02	0.486
Female student	853	0.06	0.04	0.02	0.562
Student born before 1989	853	0.10	0.05	0.01	0.490
Monthly household income > NT\$100,000	853	0.09	0.04	0.01	0.491
College-educated parent(s)	853	0.09	0.06	0.02	0.485
Parent(s) work in government	853	0.08	0.04	0.01	0.487
Ethnic minority parent(s)	853	0.08	0.04	0.01	0.494
<i>Since primary school:</i>					
Student always prioritized studies	853	0.12	0.06	0.01	0.491
Student always reviews lessons	853	0.12	0.06	0.01	0.478
Student likes new things	853	0.13	0.07	0.02	0.465
<i>During primary school:</i>					
Student was truant	853	0.08	0.04	0.01	0.498
Student had mental health issues	853	0.10	0.06	0.02	0.495
Student quarreled with parents	853	0.10	0.05	0.01	0.503
<i>Before junior high school:</i>					
Student had private tutoring	853	0.11	0.06	0.01	0.479
Family help with homework	853	0.09	0.05	0.01	0.496
Student enrolled in gifted academic class	853	0.09	0.05	0.02	0.466
Student enrolled in arts gifted class	853	0.12	0.08	0.03	0.447
Parents made efforts to place student in better class	853	0.13	0.07	0.02	0.465

*Note: This table shows the results of permutation-based class-level sorting tests, in our estimation sample containing 227 schools, 853 classrooms, and 12,816 students. For these tests, we simulate 10,000 classrooms under the null of random assignment of students to classrooms within schools, calculate the mean of pre-treatment characteristics in synthetic classroom, and construct class-level empirical p-values as the share of times synthetic classroom means were more extreme than actual classroom means relative to the schools mean. Each row presents class-level empirical p-values for a different pre-assignment characteristic. The last column shows the average p-value for all classrooms.*

**Table B.6:** *Non-Parametric Sorting Test in Estimation Sample*

	School-level regressions	Share of class-dummy joint significance test p-val. under:		
		(1)	(2)	(3)
<i>Pre-assignment characteristics:</i>				
Student test scores	227	0.06	0.04	0.03
Female student	216	0.05	0.02	0.02
Student born before 1989	227	0.12	0.03	0.01
Monthly household income > NT\$100,000	208	0.09	0.04	0.00
College-educated parent(s)	204	0.13	0.07	0.02
Parent(s) work in government	205	0.06	0.02	0.01
Ethnic minority parent(s)	179	0.06	0.02	0.01
Since primary school:				
Student always prioritized studies	227	0.12	0.06	0.01
Student always reviews lessons	227	0.10	0.06	0.02
Student likes new things	227	0.14	0.10	0.02
During primary school:				
Student was truant	227	0.10	0.03	0.01
Student had mental health issues	227	0.12	0.07	0.01
Student quarreled with parents	227	0.10	0.04	0.00
Before junior high school:				
Had private tutoring	227	0.13	0.08	0.02
Family help with homework	226	0.08	0.06	0.02
Student enrolled in gifted academic class	206	0.11	0.05	0.02
Student enrolled in arts gifted class	186	0.15	0.09	0.07
Parents made efforts to place student in better class	225	0.14	0.10	0.04

*Note: This table shows the results of non-parametric school-level sorting tests in our estimation sample containing 227 schools, 853 classrooms, and 12,816 students. School-by-school, we regress each pre-treatment characteristics on a set of class dummies, F-test them for joint significance, and calculate the share of times the F-tests p-values fall under typical significance thresholds. Each row presents class-level empirical p-values for a different pre-assignment characteristic. We use cluster-robust covariance matrices at the classroom level for each test.*

**Table B.7:** Sensitivity of Estimates to Latent Class Threshold in Posterior Probability in the Fishing Algorithm

Students	11,029	11,800	12,302	13,526	14,665	15,687

This table reports coefficient estimates of regressing student outcomes in wave 2 on standardized average peer ability in wave 1 in samples defined by taking different thresholds in the school-level posterior probability of being a defier school, as defined by our fishing algorithm. All models include school fixed effects, and students' own ability and educational inputs in wave 1. At the bottom we report Jochmans (2020)'s sorting t-statistic, noting that its reference distribution is the standard normal. T-statistics larger than critical values for a two-sided test are shown in italics for 95% confidence and in bold for 99% confidence. Standard errors are clustered at the classroom level. \*, \*\* and \*\*\* denote significance levels at the 10%, 5% and 1%.

**Table B.8:** Oster (2019) Proportional Selection on Unobservable Characteristics in Initial Sample

	Degree of selection required to explain effect of peer test scores on outcomes	
	(1)	(2)
<i>Outcomes:</i>		
Test scores	0	-0.20
School effort	0	-0.10
Initiative in class	0	-3.00
Truancy	-0.1	2.40
Cheated on exams	0	-0.50
Academic self-efficacy	0	-5.70
Mental health	0	-0.70
University aspirations	0	-1.00
University expectations	0	-1.10
Private tutoring	-0.1	0.10
Time with parents	0.1	-0.40
Conflict with parents	-0.1	-3.40
Parental strictness	-0.1	-1.60
Parental support	-0.1	-0.50
Harsh parenting	0	-4.80
Parent uni. Aspirations	-0.1	0.00
School environment	0	-0.70
Classroom hard to manage	0.1	-0.10
Teacher engagement	0	-0.90
Teacher tired of teaching	0	0.00
<i>Selection proportional to:</i>		
Balancing controls	Y	Y
W1 inputs		Y

*This table reports Oster's (2019)  $\delta$ , the share of proportional selection needed to explain away each estimate in our initial sample 332 schools, 1,241 classrooms and 14,383 students. Values of  $\delta$  between zero and one imply that, under reasonable assumption, the effect can be explained by correlated unobservable characteristics. Each cell is an estimate from a separate analysis. All estimates are calculated using Oster (2019)'s `psacalc` Stata package, and assume a theoretical maximum R-square of one. All models control for school fixed effects and student test scores in wave 1. Pre-assignment characteristics are listed in Section 4.2. Educational inputs in wave 1 are listed in Section 5.1.*

**Table B.9:** *The Effect of Peer Ability on Students' Own Ability, Using Alternative Measures of Ability*

Outcome: Student ability in wave 2 [std]					
	Measure of Ability used:				
	IRT Bayesian posterior mean of:				
	<i>Analytical</i> (1)	<i>Math</i> (2)	<i>General</i> (3)	<i>Analytical</i> (4)	<i>Math</i> (5)
Peer ability [std]	0.042** (0.018)	0.046*** (0.016)	0.048*** (0.017)	0.043** (0.019)	0.047*** (0.017)
Own ability [std]	0.389*** (0.010)	0.542*** (0.009)	0.606*** (0.009)	0.396*** (0.010)	0.558*** (0.009)
$R^2$	0.46	0.61	0.70	0.49	0.64

*Note:* This table reports coefficient estimates of regressing student's own ability in wave 2 on standardized average peer ability and own ability in wave 1 in our estimation sample containing 232 schools, 850 classrooms, and 11,029 students. The columns vary the measure of ability used for the analysis. The identification of analytical and mathematical subcomponents of ability and the Bayesian posterior mean calculation based on Item Response Theory (IRT) models, the TEPS team could also identify two highly correlated but distinct subcomponents measuring analytical ability and mathematical ability based on disjoint subsets of test questions. The IRT models were also used to produce the standardized Bayesian posterior means of the three components identifiable in the test—the general ability component and the analytical ability and mathematical ability subcomponents. All models include school fixed effects and educational inputs in wave 1. Standard errors are clustered at the classroom level. \*, \*\* and \*\*\* denote significance levels at the 10%, 5% and 1%.

**Table B.10:** *The Effect of Better Peer Ability on Students' Own Ability, Using Instrumental Variable Estimators to Account for Measurement Error in Ability*

Outcome: Student ability in wave 2 [std]			
	Measure of Ability used:		
	Analytical (1)	Mathematical (2)	Mixed (3)
Peer ability [std]	0.054* (0.029)	0.042* (0.025)	0.068* (0.029)
Instrument t-statistic of first-stage coefficient	Mathematical 30.53	Analytical 28.25	Alt. mixed 27.01

*Note:* This table reports coefficient estimates of instrumental variable regressions of student's test scores in wave 2 on standardized average peer ability in wave 1 in our estimation sample containing 232 schools, 850 classrooms, and 11,744 students. The measures of ability and the instrument vary across columns, as described in Section 6.2. All models include school fixed effects, and students' own test scores and educational inputs in wave 1. Standard errors are clustered at the classroom level. \*, \*\* and \*\*\* denote significance levels at the 10%, 5% and 1%.

**Table B.11:** *The Effect of Peer Ability on Educational Inputs, Using a Mixed Ability IV Approach*

	Mixed IV effect of peer ability [std]

*Note: This table presents some key features of junior high school in 35 countries participating in TIMSS 1999. TIMSS 1999 data is publicly available through the TIMSS 1999 International Database. This table presents means using sampling weights and Jackknife repeated replications, following the TIMSS 1999 User Guide. All features presented here are reported by school principals, except daily study hours and Math taught in small groups (cols. (4) and (5)), which is reported by students. Means for Taiwan are presented in the first row.*

## Appendix C The Fishing Algorithm

In this Appendix, we explain the steps of our Fishing Algorithm introduced in Section 4.2 in detail. We illustrate its use in the TEPS data. We also provide simulation evidence of its performance in Appendix D.

### C.1 Sorting of students into classrooms within schools in TEPS

As discussed in Section 3, Taiwan has an explicit mandate of random assignment of students to classrooms within schools. We first test whether the TEPS data is consistent with this mandate without imposing any sample restrictions and refer to this as our “initial sample”. This initial sample includes a total of 20,055 students assigned to 1,244 classrooms across 333 schools in wave 1, for whom we have data from either students, parents, teachers or school administrators’ questionnaires. Most students can be matched across questionnaires—we lose fewer than 1,000 observations due to questionnaire non-match—yet we estimate our initial tests on this unrestricted sample to limit the influence of selective questionnaire attrition.

We first run sorting tests on student wave 1 standardized test scores, as well as on each characteristic that we can unambiguously treat as pre-assignment; that is, variables capturing either fixed traits or events prior to entering junior high school.

Standardized test scores are not strictly measured pre-assignment; they were taken by students during the first weeks of the first junior high school academic year, shortly after assignment to classrooms. However, it is highly doubtful that only a few weeks’ worth of exposure to peers could generate considerable peer effects already. Moreover, these test scores were never revealed to students, parents, teachers or school administrators so there is no chance of re-sorting of classrooms after initial assignment based on the results of these exams. However, finding sorting on standardized test scores would still be consistent with students being assigned to classrooms based on other ability or academic performance measures that are either known to the parents, teachers, or school administrators. In this spirit, we analyze standardized test scores in this paper.

To run sorting tests loosely follow the within-school equation:

$$Y_{ics1} = \beta \bar{Y}_{ics1}^{-i} + \mu_s + \varepsilon_{ics1}, \quad (\text{C.1})$$

where  $Y_{ics1}$  is the characteristic of student  $i$  in class  $c$  in school  $s$  in wave 1, which is pre-determined at the time of assignment,  $\bar{Y}_{ics1}^{-i}$  is the class leave-out mean of the same variable  $Y$  at wave 1 (the classroom peer mean of characteristic),  $\mu_s$  is school-invariant unobserved heterogeneity which we account for using school fixed effects, and  $\varepsilon_{ics1}$  is a conditionally uncorrelated model error term.

The sorting statistic of interest is closely related to with the standard normal as a reference dis-

tribution in large samples. A positive over critical values in the distribution indicates positive sorting of students into classrooms based on the tested pre-determined characteristic. However, Guryan, Kroft and Notowidigdo (2009) observe that, under random assignment,  $\hat{\beta}$  presents a small negative bias which seems to disappear when controlling for school-level leave-out-mean of the characteristic in sorting tests. Jochmans (2020) shows that Guryan, Kroft and Notowidigdo (2009)’s empirical correction results in low power for detecting sorting, derives analytical expressions for this bias in within-school estimators and proposes a bias-corrected that solves this power issue. In our sorting tests, we present  $\hat{t}$  using the more commonly found Guryan, Kroft and Notowidigdo (2009) method and the very recent Jochmans (2020) improvement.

The second and third columns of Table C.1 show the sorting test statistics for all pre-determined characteristics we consider. There is plenty of evidence suggesting that students are sorted into classrooms with similar peers in the initial sample – certainly for test scores, but also for family income and parental education, intellectual curiosity during primary school, private tutoring before entering junior high school, gifted academic and art class assignment, and on parents’ efforts to influence the student’s classroom assignment. Sorting on test scores in this sample is already reason enough for thinking that estimates of higher-ability peer effects might be biased. Yet further balancing tests on higher-ability peers—which regress  $Y_{ics1}$  on  $\overline{TestScores}_{ics1}$  — also show that higher-ability peers are also related to several pre-determined characteristics at baseline. These balancing test results are shown in the last two columns of Table C.1.<sup>18</sup>

Our next step is to characterize the deviations from random assignment in this initial sample in order to hopefully correct them. In Taiwan, class assignment is tasked to schools themselves, as opposed to being done at the regional or school district level. Because of this, we suspect that deviations from random assignment in our data could come directly from having (hopefully few) non-compliant schools, and direct our efforts towards finding these schools. All results in Table C.1 suggest that, in these sorter schools, students assigned to higher-ability peers are also higher ability themselves and are also generally more advantaged in other respects. These schools might have sorted students into classrooms directly based on academic ability/performance, perhaps by assignment them to “gifted” classrooms together, and perhaps also as a response of parental pressure on the school. All these are informative insights in the next steps of our Fishing Algorithm.

---

<sup>18</sup>Note that, due to the large number of pre-treatment characteristics we test and the many students and classes in TEPS, we are more likely to find imbalances than many previous academic peer effect studies. The size of our detected imbalances is relatively small generally (very) small. In fact, simple back-of-the-envelope calculations suggest that in other datasets commonly used to estimate peer effects, such as the Project STAR data, imbalances of this size would have gone undetected.

## C.2 The Fishing Algorithm

The Fishing Algorithm is a data-driven method we developed to detect schools that are likely not compliant with Taiwan’s national mandate to randomly assign students to classrooms. The algorithm combines permutation-based measures of the degree of sorting in the data with latent-class modeling techniques. Despite seeming complex, the intuition behind the procedure is simple and its implementation is fast. Its steps are described in Box C.1.

---

**Algorithm C.1** The Fishing Algorithm

---

- 1: Identify sorted/imbalanced pre-assignment characteristics. Identify your key measure of interest and, if sorted/imbalanced, continue to step 2.
  - 2: Construct a school-level measure of sorting in your key measure of interest for each school  $s = 1 \dots S$ . We propose a modified Herfindahl-Hirschman index for concentration of the key student characteristic into classrooms in each school. Call this measure  $H_s$ .
  - 3: For each school, simulate the counterfactual  $H_s$  under random assignment of students to classrooms, while keeping school size, class size, number of classrooms and student compositions constant. Call this counterfactual assignment  $H_s^{random}$ . Use  $B$  permuted random assignments of students to classrooms to derive the school-level distributions of  $H_s$  for each school  $s$ . Using these distributions, construct the school-level share of permutations for which  $H_s$  is larger than  $H_s^{random}$  and call it  $S_s \in [0, 1]$ .  $S_s$  measures the degree of sorting of students to classrooms in each school over and above what chance would predict.
  - 4: Use latent class models to predict  $S_s$ . Since  $S_s$  is censored below at 0 and above at 1, we propose fitting finite mixture tobit regressions. Select the number of latent classes in the model using a pre-determined goodness-of-fit measure (e.g., AIC, BIC). (If available, use school-level predictors for sorter schools informed by your knowledge of the data. You can use likelihood ratio tests to decide whether these class predictors are worth including in the model.) Identify the latent class(es) associated with high  $S_s$  (close to 1); these are likely to identify sorter schools. Using model estimates, construct the school-level posterior probability of belonging to a latent sorter class. Call this measure  $P_s$ .
  - 5: Construct a sorter flag for each school based on whether  $P_s$  exceeds a pre-determined threshold. We suggest using a “most likely sorter” rule: flag schools which are most likely to belong to a latent sorter class than to any other latent class as sorter schools. Remove flagged schools from your estimation sample, call this the trimmed sample. Re-estimate your balancing and sorting tests in this sample.
- 

In the first step, we identify whether there is evidence of sorting and/or imbalance in the data. Table C.1 describes the results of these tests for the TEPS initial sample. Since our study focuses on estimating the effect of higher-ability classroom peers, we identify student test scores as our key pre-assignment characteristic for the remaining steps.

In the second step, we construct our school-level measure of sorting of students into classrooms based on standardized test scores. We base our measure on the Herfindahl-Hirschman index, the most prominent measure of market concentration in economics. In school  $s$  with classrooms

$c = 1 \dots C$ , we define our measure as:

$$H_s = \sum_{c=1}^C \left( \frac{\overline{TestScores}_{cs}}{\sum_{c=1}^C \overline{TestScores}_{cs}} \right)^2 \quad (C.2)$$

Where  $\overline{TestScores}_{cs}$  is the average standardized test score in classroom  $c$  of school  $s$ .<sup>19</sup>  $H_s$  is a measure of the concentration (or sorting) of student test scores into classrooms within each school, and it will range between  $1/C$  (if  $\overline{TestScores}_{cs}$  is identical in all classrooms) to 1 (if all students with positive test scores are together in one classroom—which is ridiculous with test scores but more easy to think of when measuring sorting by e.g., race or gender). At this point our constructed  $H_s$  includes test score sorting data for each of the 333 schools in TEPS.<sup>20</sup>

In the third step, we construct counterfactual distributions of  $H_s$  for each of the 333 schools in TEPS that reflect random assignment of students to classrooms within schools. To do this, we construct  $B = 400$  permutations of random assignment of students to classroom within each school maintaining each schools' data structure; that is, maintaining the student number and composition in each school, and the exact number and size of classrooms in each school. Ensuring the data structure is maintained is crucial for computing randomization-based statistics (Young, 2019). For each permutation  $b = 1 \dots B$  we thus end up with a measure  $H_s^{random}$  that reflects one way that school sorting *could have looked like* if classrooms were randomly assigned within schools. Since we do this  $B = 400$  times, we end up with a distribution of this school concentration index based on 400 counterfactual classroom assignments for each school. We then construct  $S_s$  for each school: the share of the 400 permutations for which the actual school concentration  $H_s$  strictly exceeds the simulated concentration under random assignment  $H_s^{random}$ . For example, in a school where the actual score concentration was larger than 350 out of 400 simulated concentrations,  $S_s$  would take the value of  $350/400 = 0.875$ .

At this point, it is important to highlight why  $S_s$  is a superior measure of classroom sorting than  $H_s$ , especially to capture sorting on characteristics that are relatively rare. To do this, imagine trying to measure sorting based on race in a school with three classrooms and one racial minority student. Even if this school fully complies with random assignment, the measure  $H_s$  will equal 1, implying full sorting. This is because, in any classroom configuration “all” minority students will be in the same classroom. The measure  $S_s$ , however, will equal 0 — implying perfect sorting — because in no permutation will  $H_s$  strictly exceed  $H_s^{random}$ . Generalizing based on this example, the key lesson is that  $S_s$  naturally normalizes classroom concentration to reflect

---

<sup>20</sup>It is important to note that by standardized test scores we mean “scores from a standardized test” rather than “test scores that have been standardized to have a mean of zero and a standard deviation of one”. Steps 3 through 5 of the Fishing Algorithm work much better if  $H_s$  is constructed from test scores (or any other measure) that is weakly positive (i.e., with support in  $[0; \infty)$  ).

**Figure C.1:** *The School-Level Concentration of Classrooms Based on Test Scores, With  $B = 400$  Classroom Assignment Permutations*

*Note:* This figure shows the school-level distribution of our measure for whether schools sort students into classrooms more strongly than chance would allow, given the school size, number and classroom size and student composition. The probability of being a sorter school is the posterior probability of being in a latent class classified as sorters by us and calculated based on a finite mixture model of school sorting using several school averages of parental characteristics as class predictors.

the rarity of the characteristic of interest at the school level, a very useful property.<sup>21</sup>

Figure C.1 shows the distribution of our school-level measure of classroom concentration based on test scores,  $S_s$ , for all 333 schools in the TEPS data. If all schools in TEPS would have perfectly complied with random assignment of students to classrooms, we would expect this to closely resemble a standardized uniform distribution. The figure suggests that most schools are likely complying with the random assignment mandate, yet a small but non-negligible share of schools show very high degree of sorting that is inconsistent with random assignment. With a quick graphical analysis of the distribution, one could conclude that schools in the rightmost part of the distribution—with  $S_s > 0.9$  which adds up to roughly 80 schools—are much more likely be defying the mandate of random assignment.

At this stage just dropping these 80 schools from our data would be rather crude. Under random assignment, we should still expect that some schools, by chance, ended up group-

<sup>21</sup>A second, perhaps subtler, lesson is that we can only interpret as evidence of strong classroom non-sorting when the characteristic of interest is prevalent in the school (i.e., when the number of students with that characteristic exceed the number of classes in the school).

ing students with similar test scores. Blindly trimming these schools could therefore lead to “over-trimming”: removing schools that have high sorting by chance. One problem with over-trimming is that it can lead to negative sorting tests in the trimmed sample. Another, perhaps more serious, problem is that it would remove legitimate variation from the estimation sample that could be crucial for identifying peer effect. These worst-case scenarios could result in a loss of power for identifying peer effects in the trimmed sample and, if peer effects are extremely non-linear, over-trimming could bias peer effect estimates downwards. In the fourth and key innovative step of our Fishing Algorithm, we try to disentangle schools that have strong sorting by chance from schools that are defying the mandate of random assignment using latent class models of  $S_s$ . Our preferred method is to fit a finite mixture model (FMM) of  $S_s$  to recover a predicted probability of being a school defying the mandate of random assignment to classrooms for each school.<sup>22</sup> One good reason for using FMM is that, based on its estimates, we can construct the posterior probability of belonging to each latent class modeled and. Once we have identified which class is likely to capture sorter schools, this gives us a direct estimate of school-level probability to be a sorter, which we then use to construct our likely sorter school flag.

For this step, there are four key choices to make: i) the correct model given the distribution of  $S_s$ , ii) the number of latent classes, iii) the class-level predictors (if any), and iv) the classification rule that flags a school as sorter. We discuss these choices and our approach to making them in turn:

1. For modelling the distribution of  $S_s$ , we opted for fitting a FMM tobit to account for the censoring of  $S_s$  at 1. For other characteristics or in other datasets where  $S_s$  shows less censoring, one can always fit beta or linear regression FMMs instead. In the TEPS data all these alternatives yield similar results.
2. We chose the number of latent classes that minimizes the Bayesian Information Criterion. In the TEPS data this was a 3-class model. Of these three classes, only one had a conspicuously large predicted mean for  $S_s$ , which was very close to 1. We identified this as the latent class of sorter schools. The other two classes had much lower predicted means for  $S_s$ , both close to 0.5. Using the Akaike Information Criterion we would have chosen a 2-class model instead; a sorter latent class with a predicted very close to 1 and a non-sorter latent class with predicted close to 0.5. Both models would have classified schools near-identically. Models with more than 3 latent classes did not improve fit much but did increase optimization complexity and often had issues converging.

---

<sup>22</sup>We have also worked on procedures that detect sorter schools based on several  $P_s$  indices — to detect, for example, one type of sorter school that sorts students to classrooms based on test scores, and a second type that sorts students based on their history of truancy—using unsupervised machine learning techniques such as hierarchical cluster analysis.

3. We chose school-level class predictors that were significantly related to  $S_s$ . In the TEPS data these are schools means for: children who report being in academically gifted classrooms, parents who push for their children to be assigned to particular classrooms, ethnic minority students, private tutoring lessons before joining junior high school, and two measures of baseline student effort. All these measures were positive predictors of belonging to the sorter latent class, most of the statistically significant at conventional levels. These predictors meaningfully improved the model performance and, since models with and without class predictors are nested, one can make the choice to include these in the final model specification based on a likelihood ratio test.
4. For flagging schools as sorters we constructed for each school the probability of belonging to the sorter latent class  $P_s$ —the class with predicted  $S_s$  close to 1—based on the FMM estimates with class predictors. We then opted for classifying sorter schools as schools which were most likely to belong to the sorter latent class than to any other class. Different thresholds can of course be justified, but this is a reasonable one with a clear a priori justification. Our model results are not sensitive to other reasonable classification thresholds such as  $P_s$  being larger than the sum of all other predicted class probabilities.

Table C.2 shows the results of the Finite Mixture Model estimation in the TEPS data. The latent class marginal means and variances suggest that the third latent class clearly identifies sorter schools, and the posterior latent class probability for this class suggests that 24.6 percent of schools might be sorters. The latent class predictor coefficients are also consistent with the third latent class identifying sorter schools, and most of these predictors are statistically significant.

Figure 2 in Section 4.2.1 shows the schools eventually flagged as sorters by our Fishing Algorithm across the distribution of  $S_s$ . We overlay the probability of being a sorter school  $P_s$  (on the right y-axis) in a scatterplot, with 0.5 as a dashed horizontal reference line. Our Fishing Algorithm flags 106 schools where  $P_s$  is largest as sorters. As expected, most flagged schools have  $S_s > 0.9$ , though a few schools with lower values of  $S_s$  are also flagged. In the TEPS data, the algorithm failed to identify non-sorter schools with very high  $S_s$ . It is possible, of course, that all these schools with high  $S_s$  are in fact sorters, yet it is more likely that the FMM class predictors are just not strong enough to discern the non-sorters among this group. As discussed above and in Section 4.2.1, this could lead to over-trimming and in fact we do see some evidence of this in Table 2, which shows sorting and balancing tests in our sample trimmed of the 106 schools flagged as sorters. Yet evidence of over-trimming is not strong enough to be concerning.

As a final point in this appendix, we show that out applying our Fishing Algorithm in the TEPS data does not introduce any evident selectivity in our estimation samples. Table C.3 shows that our initial sample including all the TEPS data remains very similar to our trimmed sample—which includes all information from schools not flagged as sorters by our Fishing Algorithm, and also remains similar to the our most restricted estimation sample—which includes only students for which we observe test scores, educational inputs and other key characteris-

tics in both TEPS waves. The only difference is that the more restrictive samples have slightly larger schools, which can easily happen if smaller schools are more likely to systematically sort students into classrooms (because e.g., they are more likely to be special schools with exceptions to the national mandate, or have lower invigilance).

**Table C.1: Balancing and Sorting Tests on the TEPS Initial Sample**

Treatment Variable:	Sorting tests (t-statistic)			Balancing tests	
	Students	Peer outcome leave-out mean	Peer ability leave-out-mean [std]	Coef.	Std. err.

No. of students (approx.)	20,055	14,044	11,029

*Note: This table presents summary statistics of student and parent demographic characteristics in the initial TEPS sample, the sample trimmed using our Fishing Algorithm, and the final estimation sample.*

## Appendix D Fishing Algorithm in Simulated Data

In this appendix, we use simulated data to validate our fishing algorithm and investigate its performance. Ideally, we would want to provide evidence from Monte-Carlo simulations of the performance of the algorithm in detecting schools that systematically sort students into classrooms. Unfortunately, we cannot provide Monte-Carlo evidence over many simulations—say, over 10,000 realizations of the same data generating process—since i) Steps 4 and 5 of the algorithm require making some decisions that cannot be automatized (see Box C.1 in Appendix C) and ii) the finite mixture models in Step 4 often have convergence issues that demand making additional decisions, such as trying out different optimization procedures, grid search across different parameter values, or try out various initial latent class probabilities. Nevertheless, we provide as extensive evidence of the performance of our fishing algorithm as our setting allows, and highlight lessons learned along the way. These lessons will prove useful to researchers intending to implement our fishing algorithm in their data. In addition, we have coded flexible simulation programs in Stata which will be available with the published version of this paper.

### D.1 The Data Generating Process (DGP) for our Simulations

We simulate data that closely follows our empirical setting in Taiwan: students are divided into schools and, within schools, assigned to classrooms. The only characteristic that varies across students is their ability. Classrooms are simple groupings of students within schools. Students in the same classroom can end up being similar or dissimilar to one another, depending partly on chance and partly on whether their school randomly assigns students to classrooms. Schools can differ in two dimensions: whether they actively sort students of similar ability into classrooms (*sorter* schools) or not (*non-sorter* schools), and—for sorter schools—the degree to which they sort students into classrooms. In addition, we also simulate a school-level variable that predicts whether the school is sorting or non-sorting. These three parameters—the number of sorting schools, the strength of sorting within sorting schools, and the strength of the sorting school predictor—are the key parameters we vary across our simulations. All other parameters, such as school size and classroom size, are kept constant across DGPs.

Specifically, for each DGP we simulate data from 300 schools. We stochastically vary the number of students across schools between 50 and 70 with an independent uniform distribution,  $U[50, 70]$ , mostly as a legacy for implementing the Guryan, Kroft and Notowidigdo (2009) sorting test. Their method accounted for a small negative bias in classical sorting tests by controlling for school-level leave-out-mean of student ability, but this correction only works well when there is variation in school size in the data. For our exercises, however, we implement instead the solution proposed by Jochmans (2020), who derives analytical expressions for this negative bias and proposes a bias-corrected test with better power and implementable without school-size variation. Once we have schools filled with students, we assign ability to students according to  $ability \sim U[0, 1]$ .

At this point, we randomly determine which schools are the sorting schools that sort students into classrooms based on *ability*, and which schools are non-sorting schools. The number of sorting schools,  $N_{\text{sorting}}$ , is the first key parameter we vary across DGPs. Here we also generate *predictor*, the variable predicting whether a school is a sorter or a non-sorter, given by:

$$\text{predictor} = 1\{\text{sortingschool}\} \times p + U[0, 1] \times (1 - p)$$

where  $1\{\text{sortingschool}\}$  is a dummy variable which flags sorting schools,  $p \in [0, 1]$  is a *predictor strength* parameter, and  $U[0, 1]$  is another independent random uniform. If  $p$  equals 1, *predictor* will be a perfect determinant of whether a school is systematically sorting students into classrooms; if  $p$  equals zero, *predictor* will be completely uninformative for school type. The predictor strength  $p$  is the second key parameter we vary across DGPs.

Within each school we then sort students based on the *sortingstrength* parameter in this school, and then sequentially assign them to similar-sized classrooms of roughly 15 students. *sortingstrength* is key for simulating student sorting into classrooms for some schools but not others, as is defined as:

$$\text{sortingstrength} = \begin{cases} \theta \text{ability} + (1 - \theta)U[0, 1] & \text{if student is in a sorting school} \\ U[0, 1] & \text{otherwise} \end{cases}$$

where  $\theta \in [0, 1]$  is the parameter that governs the sorting strength in sorting schools and we vary it across DGPs. The way this parameter works is best explained with a few examples.

When  $\theta$  is one, *sortingstrength* equals *ability* in sorting schools and a random uniform for non-sorting schools. This implies that in sorting schools, students will be assigned to classrooms based on their *ability*, with the first classroom having the top 15 students, the second classroom the top 15 among the remaining students, and so on. This simulates very strong sorting of students into classrooms in a scenario we refer to as “perfect stacking”. In non-sorter schools, students will be randomly assigned to classrooms. If instead  $\theta$  is zero, *sortingstrength* becomes a random uniform for all schools (sorting and non-sorting, resulting in random assignment of students to classrooms across the entire simulated data. Values of  $\theta$  between zero and one will vary the strength of sorting, or stacking, in sorting schools while keeping random assignment in non-sorting schools. This  $\theta$  is the second key parameter we vary across DGPs.

To make sure there is enough identifying variation in peer aggregates of *ability*, we ensure that no classroom has fewer than 10 students—which can happen because initial classroom size is set to 15 but variation in school size can occasionally lead to a classroom of fewer than 10 students. When this happens, we randomly redistribute students in these small classrooms to all other remaining classrooms, such that classrooms are always larger than 15 students.

We test the performance of our fishing algorithm using simulated data from three versions of our DGP that correspond to cases of particular interest for an econometrician interested in applying our method:

1.  $N_{\text{sorting}} = 50; \theta = 0.8; p = 0.8$  : 50 strongly sorting schools with a good sorting predictor
2.  $N_{\text{sorting}} = 50; \theta = 0.8; p = 0.1$  : 50 strong sorting schools with a weak sorting predictor
3.  $N_{\text{sorting}} = 300; \theta = 0.15$  : all schools are weak sorters, with a good sorting predictor

The first is an ideal case where the researcher can detect the few schools that violate random assignment in the data, and has access to good enough predictors to detect whether a school is sorting systematically students. The second case showcases the limitations of our fishing algorithm when the researcher does not have access to reasonable predictors of sorter schools. The third case simulates the unfortunate situation where *all* schools sort students into classrooms, enough to invalidate random assignment in the data but with no hopes of being able to fish out sorter schools with our method—or any other for that matter.

## D.2 Performance of the Fishing Algorithm

After producing data using this DGP, we then i) test the degree of sorting in the simulated data, ii) run our fishing algorithm following the steps in Box C.1, iii) evaluate the performance of our fishing algorithm in detecting sorter schools in the simulated data, and iv) estimate the degree of sorting in the data once the detected sorter schools are removed. These four sets of results are presented in Panels A, B, C and D in the tables below.

We simulate five different realizations of each DGP and present the results of our fishing algorithm for each. For each simulation, we present our results in columns (1) through (5) of the tables below. The downside of this approach is that it produces less systematic evidence of the performance of our algorithm than would Monte Carlo simulations. The upside, apart from being feasible, is that we can demonstrate the several decisions required from the researcher to use our method, explain the reasoning behind them, and showcase results of situation when, by chance, our method does not perform well.

### Case 1: Few Strong Sorter Schools and a Strong Class Predictor

Table D.1 shows the performance of the Fishing algorithm in five simulated datasets with 50 strongly sorting schools and access to a good predictor for whether schools are sorters. Panel A shows Jochmans' (2020) sorting test t-statistic estimated using the simulated student-level data. When positive and larger than critical values of the standard normal distribution, these t-statistics indicate positive sorting of students into classrooms based on ability. As expected, our simulated data shows strong evidence of sorting (first row) and this evidence is coming solely from the few sorter schools (second and third rows).

Panel B shows the steps to select the best Finite Mixture Models (FMM) to detect sorter schools. These FMMs are estimated using school-level data where the outcome is our measure of ability concentration in classrooms ( $S_s$ , see Appendix C). We first estimate FMMs with 2, 3, and 4 potential latent classes. We select the best among these models based on goodness of fit, using the smallest Bayesian Information Criteria (BIC); the BIC of the preferred model is marked in **bold** in each column.

**Table D.1:** Fishing Algorithm Performance in Five Simulated Datasets with 50 Strongly Sorting Schools ( $N_{\text{sorting}} = 50, \theta = 0.8$ ) and Access to a Good Predictor for Whether Schools Are Sorters ( $p = 0.8$ )

*In Panels A and D, numbers in bold mark values larger than the 5% critical value in the reference a standard normal distribution. In Panel B, numbers in bold correspond to the smallest Bayesian Information Criterion (BIC) and the largest predicted outcome mean, used to select the preferred model, and numbers in italics correspond to models that did not comply with convergence criteria. A missing Likelihood Ratio (LR) test p-value is missing in Panel B, indicating that either the model using sorting predictors for the latent classes or the model without predictors did not converge (almost always the former).*

FMMs often have convergence issues—one of the reasons why we cannot produce complete Monte Carlo evidence in this Appendix. We mark models that failed to converge in *italics*.

After choosing the preferred number of latent classes based on the BIC, we then choose whether the preferred model will include the variable *predictor* as a latent class predictor. For this, we estimate FMMs with and without this latent class predictor and use a Likelihood Ratio (LR) test to choose between these nested models. Rejecting the null that the models are equal leads us to choose the model that includes *predictor* as a latent class predictor. Here too, we have missing values for the p-value of this LR test when either model does not converge. Finally, we show the marginal means for each class—the average outcome predicted for schools in each latent class—in the preferred model. These correspond to the predicted level of classroom concentration in schools in each latent class. We interpret the latent class(es) with unusually high predicted means as those that identify sorter schools. These are also marked in **bold**.

There are three broad lessons from Panel B of Table D.1. First, models with two or three latent classes are generally preferred, and models with four latent classes often have convergence issues. This relatively simple latent class structure is partly a direct result of our DGPs—which have, in fact, two latent classes of sorter and non-sorter schools—yet it confirms that the FMMs do not tend to over-fit latent classes in the data. Second, models that use latent class predictors also suffer convergence issues. This is a potential shortcoming, since we later show that these predictors can meaningfully improve the performance of our fishing algorithm. Third, there is almost always a latent class with a clearly larger predicted sorting strength, and the closer this prediction is to 1 it is that this class identifies sorter schools.

Panel C summarizes the performance of the preferred FMM for classifying sorter schools—schools which, in violation of random assignment, systematically sort students into classrooms. We flag sorter school as those for which the posterior latent class probability for the sorter class is larger than the sum of all the other posterior latent class probabilities, as described in Appendix C. We report four standard indicators to describe the performance of our algorithm at detecting schools that systematically sort students into classrooms: i) the number of schools classified as sorters (out of 300), ii) the percentage of schools that are correctly classified as sorter schools by the fishing algorithm and are truly sorter schools, iii) the probability of being wrongly classified as a sorter school and actually being a non-sorter school (false positives), and iv) the probability of being classified as a non-sorter school and truly being a sorter school (false negative). Overall, the algorithm performs very well for this DGP: in 2 out of 5 simulations, the algorithm perfectly separates sorter and non-sorter schools (col. (1) and col. (4)), and in 2 additional simulations it identifies no false negatives and only a few false positives (col. (3) and col. (5)).

In column (2) the fishing algorithm somewhat fails: the algorithm indicates that the majority of schools as sorters, over 50% of which are actually non-sorter schools. This failure is not complete, however, in the sense that the algorithm only becomes too stringent, but does not misclassify sorter schools as compliant. The good news is that our exercise reveals why this failure occurred: the selected FMM model in this instance could not use as a latent class predictor to identify the latent class with sorter schools, and consequently the predicted sorting strength

for this model is 0.73, well below that of all other models. The lesson for researchers applying our method here is that having access to a good predictor of whether schools are sorting will meaningfully improve the performance of our fishing algorithm, even in settings with few strongly sorting schools. Panel D shows the sorting test performance from Jochmans (2020) back in the student-level simulated data in non-sorter schools—those classified as non-sorters by the fishing algorithm. For the two models with perfect performance (Columns (1) and (4)), we see that the t-statistics match the non-sorter t-statistics in Panel A. For the other three models, we see negative and significant t-statistics (Columns (3) and (5)); much more negative for the worst-performing model (Column (2)).

Negative and significant t-statistics of sorting tests become increasingly more frequent as the rate of false positives increases – that is, the probability of wrongly classifying non-sorting schools as sorter schools. In Appendix C, we call this situation “over-trimming”, corresponding to situations when the fishing algorithm wrongly excludes schools that are actually compliant with random assignment. The issue with over-trimming is that it could lead to censoring the distribution of peer effects.

Importantly, our algorithm can be used as a diagnostic tool for over-trimming, since a clear sign of over-trimming is a “flipping” sign of Jochmans (2020)’s t-statistic: a positive and significant t-statistic in the untrimmed data (as in Panel A) and a negative and significant t-statistic in the trimmed data (as in panel D). When this occurs, we suggest going back to the FMM specification to improve the classification performance, either by changing the number of classes or by exploring additional and hopefully better class predictors. An important early sign that the algorithm is able to discern sorter from non-sorter schools is a high predicted sorting strength for at least one latent class, like in Column (1), and Columns (3) to (5) in Panel B.

## **Case 2: Few Strong Sorter Schools and a Weak Class Predictor**

Table D.2 shows the performance of our algorithm in a DGP where there are still 50 strongly sorting schools, but the researcher only has access to a much weaker predictor of whether schools are sorters. This reflects the situation of researchers with either limited data or limited institutional knowledge to construct such predictors.

Panel A confirms that our simulated data conform to the intended DGP. Panel B illustrates that i) in these data the FMMs generally choose simpler 2-class structures, that ii) even with a much weaker predictor the FMMs tend to prefer models with class predictors, but that iii) the predicted sorting strength for the high-sorting class is much weaker (between 0.73 and 0.78) than when a good class predictor is available (in Table D.1). As a direct result, Panel C shows much higher rates of misclassification, driven entirely by a higher rate of non-sorter schools identified as sorters; all sorter schools are always correctly classified. As explained above, this will lead to over-trimming, Panel D confirms the presence of over-trimming: we find strong evidence of negative sorting in classified non-sorter schools, and positive sorting in the classified sorter

schools. In sum, Table D.2 corroborates the importance of having a strong sorting predictor for good performance of our fishing algorithm, but it also indicates two useful diagnostics that can tell the researcher whether the algorithm is likely to be performing poorly: a relatively low predicted sorting strength for the high-sorting latent class, and a strong flipping for the Jochmans (2020) sorting t-statistic for the classified non-sorters subsample. Compared to the findings of Table D.1, the findings of Table D.2 indicate that finding one or multiple strong class predictors is crucial for preventing the algorithm from over-trimming the sample.

**Table D.2:** Fishing Algorithm Performance in Five Simulated Datasets with 50 Strongly Sorting Schools ( $N_{\text{sorting}} = 50, \theta = 0.8$ ) but Only a Weak Predictor for Whether Schools Are Sorters ( $p = 0.1$ )

A missing Likelihood Ratio (LR) test p-value is missing in Panel B, indicating that either the model using sorting predictors for the latent classes or the model without predictors did not converge (almost always the former).*

### Case 3: Weak but Generalized Sorting

Table D.3 shows the performance of our fishing algorithm in a DGP that simulates sorting in all schools, weaker relatively to the previous DGP but strong enough that it would be detected by Jochmans (2020) t-statistic. This corresponds to setting with generalized violations of random assignment, such that no natural experiment could be salvaged from the data using our algorithm.

**Table D.3:** *Fishing Algorithm Performance in Five Simulated Datasets with All Weakly Sorting Schools ( $N_{\text{sorting}} = 300, \theta = 0.15$ )*

Simulation number =	(1)	(2)	(3)	(4)	(5)
<b>Panel A: Sorting t-statistic in student-level data if DGP were known</b>					
Jochmans (2020) sorting t-statistic:

Predicted sorting strength measure for:					
class 1	0.16	0.15	0.09	0.13	0.05
class 2	0.56	0.41	0.52	0.52	0.38
class 3	<b>0.93</b>	0.72	<b>0.92</b>	<b>0.90</b>	0.81
class 4	-	<b>0.95</b>	-	-	<b>0.96</b>
<b>Panel C: Selected FMM model performance for defier classification</b>					
Schools identified as defiers	79	66	82	107	46
Correctly classified schools (as %)	26.3	22.0	27.3	35.7	15.3
Pr[Non-sorter school — Defier]	-	-	-	-	-
Pr[Sorter school — Complier]	-	-	-	-	-
<b>Panel D: Sorting t-statistics in student-level data in classified schools</b>					
Jochmans (2020) sorting t-statistic:					
for classified complier schools	<b>-4.7</b>	<b>-3.6</b>	<b>-3.9</b>	<b>-4.7</b>	<b>-3.2</b>
for classified defier schools	<b>6.7</b>	<b>6.9</b>	<b>7.5</b>	<b>7.5</b>	<b>5.6</b>

*In Panels A and D, numbers in bold mark values larger than the 5% critical value in the reference a standard normal distribution. In Panel B, numbers in **bold** correspond to the smallest Bayesian Information Criterion (BIC) and the largest predicted outcome mean, used to select the preferred model, and numbers in italics correspond to models that did not comply with convergence criteria. A missing Likelihood Ratio (LR) test p-value is missing in Panel B, indicating that either the model using sorting predictors for the latent classes or the model without predictors did not converge (almost always the former).*

Panel A confirms that our simulated data conforms to this setting, producing t-statistics that significant around the 1% level. Panel B shows that i) the FMMs in this setting tend to choose 3-

and 4-class structures, ii) the sorter school predictor is never statistically significant at conventional levels, which was to be expected since all schools are sorters, and iii) the predicted sorting strength in the high-sorting latent class is higher than in Table D.2 but lower than in Table D.3. This high predicted sorting strength results in relatively few schools identified as sorters, as show in Panel C. Because the FMMs classify as sorters the schools where the strongest sorting occurs, Panel D again shows strong flipping in the Jochmans (2020) t-statistic.

Overall, Table D.3 indicates that situations where all schools sort students into classrooms (generalized sorting) compared to clustered sorting (cases 1 and 2) are characterized by i) relatively complex latent class structures, ii) relatively low model fit yet iii) high predicted sorting strengths for the high-sorting latent class even in the absence of good sorting school predictors (Panel B), and iv) flipping of the Jochmans (2020) sorting t-statistic for identified non-sorter schools (Panel D).

### **D.3 A Practitioner’s Guide for Researchers Wanting to Use our Fishing Algorithm**

Our fishing algorithm combines several intuitive steps which are nonetheless somewhat technically complex. Drawing on the lessons illustrated in this section and on our own experience in developing this algorithm, we make the following suggestions to researchers intending to use our method:

1. Strive to find predictors of whether a school sorts students into classroom, even if these predictors are not perfect. Good predictors will meaningfully improve the performance of our method, even if it can still be applied without them. Place more trust in applications with institutionally sound sorting predictors that are also statistically and quantitatively strong inputs in your latent class model.
2. Your latent class that captures sorting schools will have a predicted sorting strength close to or exceeding 1. By the nature of our measure of sorting strength, sorting schools should have strengths very close to or greater than 1. Latent classes with predicted sorting strengths much below 1 are therefore more likely to also capture non-sorting schools, increasing over-trimming problems. If your latent class model is not identifying classes with high enough predicted sorting strengths, this could be a sign that i) the class structure is not complex enough (solved by testing models with more latent classes), ii) your sorting school predictors are not good enough (solved by finding better predictors or a better structure for existing ones), or iii) sorting is too widespread in your data (only solved, sadly, by finding other data that reflects a better natural experiment).
3. Beware of sorting test flipping. Sorting test flipping—a large and positive sorting t-statistic in the whole data and a large and negative sorting t-statistic in the subsample of identified non-sorter schools—is a sign of either over-trimming or widespread sorting.
